Abstract. We develop a spectral-element method (SEM) for simulating dynamic rupture on rate-and-state faults and use it to study how the rupture is affected by a shallow fault region of steady-state velocity-strengthening friction. Our comparison of the developed SEM and a spectral boundary-integral method (BIM) for an anti-plane (two-dimensional) test problem shows that, for the finest resolution we use, the two methods produce virtually identical solutions, with negligible differences in rupture arrival times and peak slip velocities (less than 0.05% of their absolute values). The convergence with grid reduction of the developed SEM is comparable to that of BIM. We also use the test problem to compare numerical resolution required for different state evolution laws and for linear slip-weakening friction. Using our three-dimensional implementation of the methodology, we find that a shallow velocity-strengthening fault region can significantly alter dynamic rupture and ground motion. The velocity-strengthening region suppresses supershear propagation at the free surface occurring in the absence of such region, which could explain the lack of universally observed supershear rupture near the free surface. In addition, the velocity-strengthening region promotes faster fall-off of slip velocity behind the rupture front and decreases final slip throughout the entire fault, causing a smaller average stress drop. The slip decrease is largest in the shallow parts of the fault, resulting in a depth profile of slip qualitatively consistent with observations of shallow co-seismic slip deficit. The shallow velocity-strengthening region also reduces the amplification of strong ground motion due to a low-velocity bulk structure.

1. Introduction

Understanding complex and realistic scenarios of seismic and aseismic slip demands accurate and efficient numerical models that incorporate appropriate fault constitutive laws. Rate- and state-dependent friction laws have been widely used to simulate and explain various earthquake phenomena including earthquake nucleation, post-seismic slip, foreshocks, aftershocks, and aseismic transients [e.g., Marone et al., 1991; Dieterich, 1994; Ben-Zion and Rice, 1997; Marone, 1998; Lapusta and Rice, 2003; Liu and Rice, 2005; Kaneko and Lapusta, 2008; Dieterich, 2007, and references therein]. A common approach to model slip on a rate-and-state (RS) fault is to employ boundary-integral methods (BIMs). In BIMs, field quantities are considered only at the boundary of a domain, and integral expressions are used to account for elastic interactions with the surrounding media. In the framework of BIM, nucleation, rupture propagation, and arrest of earthquakes have been successfully modeled [e.g., Ben-Zion and Rice, 1997; Lapusta et al., 2000]. However, these studies have been mostly restricted to planar faults embedded into a uniform elastic space. At the same time, observations point to complicated crustal structures with variable bulk properties, fault damage zones, and non-planar fault geometries. It is important to include those factors into earthquake models, combining them with laboratory-derived constitutive fault relations such as RS friction.

Finite-element methods (FEMs) and, in particular, spectral-element methods (SEMs), can incorporate variable bulk properties and more complex fault geometries. They have been used to simulate single-earthquake scenarios, mostly with linear slip-weakening (LSW) friction [e.g., Oglesby et al., 1998; Aagaard et al., 2001; Ampuero, 2002; Festa and Vilotte, 2006; Madariaga et al., 2006]. The application of SEM to wave propagation problems is well developed [Komatitsch and Vilotte, 1998; Komatitsch and Tromp, 1999] and has been recently reviewed by Komatitsch et al. [2005] and Chaljub et al. [2007]. SEMs combine the flexibility of FEMs with high numerical accuracy due to the use of higher-order Lagrange interpolants on Gauss-Lobatto-Legendre (GLL) points that mimic the behavior of the Legendre basis [Komatitsch and Vilotte, 1998; Komatitsch and Tromp, 1999]. Furthermore, the SEMs with a diagonal mass matrix reduce computational costs associated with solving a large linear system and result in relatively simple parallel implementation. The method is well suited for describing surfaces of displacement discontinuity with mixed traction-displacement interface conditions (e.g., faults) by the split-node technique, as in FEMs [Oglesby et al., 1998; Aagaard...
et al., 2001] and some finite difference methods [Andrews, 1999; Day et al., 2005]. Fault surfaces with the split-node technique have been implemented in 2D SEMs [Ampuero, 2002; Vilotte et al., 2006], and SEMs with the split-node technique have been successfully applied to wave propagation across compliant faults [Haney et al., 2007] and to earthquake source dynamics [Festa and Vilotte, 2005; Madariaga et al., 2006].

In section 2, we present a SEM algorithm for modeling dynamic rupture on a RS fault. The 3D SEM we use was originally developed for wave propagation by Tromp [1999]; our work is an extension of the study by Ampuero [2002] that incorporated a LSW fault boundary into that SEM framework. We have extended the formulation to RS faults. To validate the developed SEM approach, we have conducted detailed comparison of SEM and BIM simulation results obtained for an anti-plane problem (section 3). Incorporating RS faults into a SEM formulation requires a semi-implicit numerical scheme which makes the implementation more challenging than that for LSW friction.

Using the developed formulation, we have investigated the effect of velocity-strengthening fault friction in the shallow portion of a fault on dynamic rupture scenarios (section 4). Accumulating evidence supports the presence of velocity-strengthening friction at shallow depths. In laboratory experiments, rock friction at low normal stress typically exhibits velocity-strengthening behavior due to unconsolidated fault gouge [e.g., Marone et al., 1991; Marone, 1998]. Theoretical studies have shown that velocity-strengthening friction responds to loading with stable sliding and does not allow for spontaneous nucleation of frictional instabilities [Rubin, 1983; Rice and Rubin, 1983]. Hence, studies of interseismic shallow creep [e.g., Lyons et al., 2002], shallow aftershock of large earthquakes [e.g., Marone et al., 1991; Marone, 1998; Hsu et al., 2006], and the deficit of seismicity at shallow depths [e.g., Shearer et al., 2005] provide indirect observational evidence for velocity-strengthening fault rheology at shallow depths. It is important to understand how velocity-strengthening friction at shallow depths affects earthquake rupture dynamics and, as a consequence, ground motion and seismic hazard assessment in the vicinity of active faults. Furthermore, the shallow velocity-strengthening region may also be relevant for tsunami earthquakes in subduction zones as it may slow down the up-dip propagation of rupture, boost the low-frequency content, and promote tsunami generation [Polet and Kanamori, 2000; Seno, 2002].

In addition, a typical Earth bulk structure has strong variation of elastic parameters with depth. The reduction of elastic moduli near the free surface results in ground-motion amplification, and thus it has important consequences for seismic hazard [e.g., Olsen, 2000]. Such bulk variations cannot be accommodated with existing BIM formulations, while SEM can incorporate them with ease. We have simulated dynamic rupture scenarios on a fault embedded in a layered bulk structure and studied how the peak ground motion at on- and off-fault sites is affected by the bulk structure combined with different fault rheologies (section 5).

2. A SEM algorithm for simulations of dynamic rupture on rate-and-state (RS) faults

2.1. Discretized elastodynamic relations

In SEM, the geometry of the mesh elements is represented by the product of low-degree Lagrange polynomials like in the classical FEM, while the field-approximation function is represented by the product of high-degree Lagrange polynomials defined on the Gauss-Lobatto-Legendre (GLL) points. The choice of coincident nodes for interpolation and numerical integration results in a diagonal mass matrix of the discretized domain, reducing the computational costs associated with solving a large linear system and making its parallel implementation relatively simple.

The discretization of the weak form of the equation of motion leads to the matrix equation:

$$ M\ddot{u} = -Ku + B\tau , $$

(1)

where M and K are the mass and stiffness matrix respectively, given by Komatitsch et al. [2005] (equation (57) and (59)), the fault-boundary matrix B is described in appendix A, $\tau = T - \tau_{\text{ext}}$ is the relative traction vector on the fault, T is the total traction, and $\tau_{\text{ext}}$ is the traction on the fault that corresponds to the reference zero-displacement state. Vectors $u$, $\dot{u}$, and $\ddot{u}$ collect the values of displacements, particle velocities, and accelerations, respectively, of all the computational nodes of the bulk mesh.

Our time discretization scheme is based upon the explicit acceleration Newmark scheme:

$$ u_{n+1} = u_n + \Delta t \ddot{u}_n + \frac{\Delta t^2}{2} \dddot{u}_n , $$

(2)

$$ M\ddot{u}_{n+1} = -Ku_n + B\tau_{n+1} , $$

(3)

$$ \dddot{u}_{n+1} = \dddot{u}_n + \frac{\Delta t^2}{2} \dddot{u}_n + \dddot{u}_{n+1} / 2 , $$

(4)

where the subscripts “n” and “n+1” refer to the number of the time step. Given all the quantities at the n-th time step, we would like to obtain the quantities at the (n+1)-th time step. The non-trivial advance is to obtain $\tau_{n+1}$ in (3) on the fault simultaneously with fault constitutive relations. Combining (3) and (4), one obtains

$$ \dddot{u}_{n+1} = \dddot{u}_{n+1}^\text{free} + \frac{\Delta t}{2} M^{-1} B\tau_{n+1} , $$

(5)

where

$$ \dddot{u}_{n+1}^\text{free} = \dddot{u}_n + \frac{\Delta t}{2} (\dddot{u}_n - M^{-1} K u_{n+1}) $$

(6)

is the “free velocity” that would prevail if the traction on the fault suddenly vanished, creating free-boundary conditions. We now write relation (5) for the fault nodes with the signs indicating the values of field variables on the two sides of the fault (Figure 1):

$$ \dddot{u}_{n+1}^\pm = \dddot{u}_{n+1}^\text{free} + \frac{\Delta t}{2} M^{-1} B \tau_{n+1}^\pm , $$

(7)

Subtracting the minus side from the plus side, and using the sign convention $\tau = -\tau^+ = \tau^-$, where $\tau^\pm$ are defined with respect to the outward normal from the fault boundary $\Gamma_\pm$ (Figure 1), we obtain

$$ \delta_{n+1} = \delta_{n+1}^\text{free} - Z^{-1} \tau_{n+1} , $$

(8)

where vectors $\delta$, $\dot{\delta}$, and $\ddot{\delta}$ refer to the slip, slip velocity, and slip acceleration, defined as the difference between values of displacement, velocity, and acceleration, respectively, of corresponding split nodes across the fault plane (e.g., $\delta = u^+ - u^-$ and $\ddot{\delta}^\text{free} = \dddot{u}^\text{free} - \dddot{u}^\text{free}$), and Z is the fault impedance matrix given by

$$ Z^{-1} = \frac{\Delta t}{2} (M_+^{-1} B_+ + M_-^{-1} B_-) . $$

(9)

Note that for cases we consider in this study, the fault-normal component of traction T remains unchanged, and hence the fault-normal components of $\tau$ and $\delta$ are zero.
The matrices $M$ and $Z^{-1}$ are diagonal, and $B_+ = B_-$ for conformal meshes. Solving (8) for $\tau_{n+1}$ gives

$$\tau_{n+1} = Z \delta_{n+1}^{\text{free}} - Z \delta_{n+1}.$$  \hspace{1cm} (10)

The expression (10) is a local relation which can be solved node by node on the fault. It is convenient to rewrite (10) in terms of total traction, $T = \tau + \tau_o$:

$$T_{n+1} = \tau_o + Z \delta_{n+1}^{\text{free}} - Z \delta_{n+1}$$
$$\equiv T_{n+1} - Z \delta_{n+1},$$  \hspace{1cm} (11)

where $\delta$ is the “stick traction” that would prevail if there were a sudden slip arrest.

2.2. Rate and state (RS) friction laws

Rate- and state-dependent friction laws were developed to incorporate observations of rock friction experiments at relatively low sliding rates of $10^{-3}$ to $10^{-6}$ m/s [Dieterich, 1978, 1979; Ruina, 1983; Blanpied et al., 1995, 1998; Marone, 1998]. In the situations with constant effective normal stress $\sigma$, the shear strength $T$ is often expressed as

$$T = \psi(\delta, \theta)$$
$$= \sigma \left[ f_0 + a \ln \left( \frac{\delta}{\delta_0} \right) + b \ln \left( \frac{\delta_0 \theta}{L} \right) \right],$$  \hspace{1cm} (12)

where $a > 0$ and $b$ are RS constitutive parameters with magnitudes of the order of 0.01, $\delta$ is the magnitude of slip velocity, $f_0$ is a reference friction coefficient corresponding to a reference slip velocity $\delta_0$, $\theta$ is a state variable which is typically interpreted as the average age of the population of contacts between two surfaces, and $L$ is the characteristic slip for state evolution [Dieterich, 1978, 1979; Rice and Ruina, 1983; Ruina, 1983; Dieterich and Kilgore, 1994]. Two types of state-variable evolution laws are commonly used in modeling:

$$\frac{d\theta}{dt} = 1 - \frac{\dot{\delta} \theta}{L} \quad \text{(aging law)},$$  \hspace{1cm} (13)

$$\frac{d\theta}{dt} = -\frac{\dot{\delta} \theta}{L} \ln \left( \frac{\delta \theta}{L} \right) \quad \text{(slip law)}.$$  \hspace{1cm} (14)

The parameter combination $a - b < 0$ corresponds to steady-state velocity-weakening friction and can lead to unstable slip, whereas $a - b > 0$ corresponds to steady-state velocity-strengthening and leads to stable sliding [Rice and Ruina, 1983; Ruina, 1983]. Throughout this article, we omit the words “steady-state” and simply refer to velocity weakening/strengthening.

In expression (12), shear frictional strength $T$ is undefined for slip velocities $\delta = 0$, which is unphysical. To regularize (12) near $\delta = 0$, we follow the approach of Rice and Ben-Zion [1996], Ben-Zion and Rice [1997], and Lapusta et al. [2000] in using a thermally activated creep model of the direct effect term $a \ln \left( \frac{\delta}{\delta_0} \right)$ to obtain

$$T = \psi(\delta, \theta)$$
$$= a \sigma \ln \left( \frac{\delta_0 \theta}{L} \right) \exp \left[ \frac{f_0 + b \ln \left( \frac{\delta_0 \theta}{L} \right)}{a} \right].$$  \hspace{1cm} (15)

This regularization is used in our simulations. It produces a negligible change from (12) in the range of slip velocities explored by laboratory experiments; the difference in $\delta$ at $\delta = \delta_0$ is of the order of exp($-2f_0/a$) or less, and the typical value of $f_0/a$ in this study is 40.

2.3. Updating scheme: advancing one evolution time step

We have developed an updating scheme, based upon the explicit Newmark method described in section 2.1, appropriate for the RS fault boundary condition. Here, we discuss how values of field variables are updated over one evolution time step. Suppose that the discretized values of field variables are known at the $n$-th time step. To find the values of the field variables at the $(n+1)$-th time step, we perform the following steps.

1. Update the values of displacements, based on the known values at the $n$-th time step:

$$u_{n+1} = u_n + \Delta t \dot{u}_n + \frac{1}{2} (\Delta t)^2 \ddot{u}_n.$$  \hspace{1cm} (16)

2. Perform the partial update of the particle velocity field in (4) by computing

$$\dot{u}_{n+1} = \dot{u}_n + \frac{1}{2} (\Delta t) \ddot{u}_n.$$  \hspace{1cm} (17)

3. Compute the “stick” traction in (11):

$$u_{n+1}^{\text{free}} = u_{n+1}^{*} - \frac{\Delta t}{2} (M^{-1}Ku_{n+1})$$
$$T_{n+1} = \tau_o + Z \delta_{n+1}^{\text{free}}.$$  \hspace{1cm} (18)

4. Determine the first prediction of the state variable, $\theta_{n+1}^{*}$. By integrating the evolution law (13) or (14) with the constant magnitude $\delta_n$ of slip velocity $\delta_n = u_n^* - u_n^-$ during the time step, we obtain

$$\theta_{n+1}^{*} = \theta_n + \frac{\Delta t}{L} \left( 1 - \exp \left( -\frac{\delta_n \Delta t}{L} \right) \right)$$
$$\exp \left( -\frac{\delta_n \Delta t}{L} \right).$$  \hspace{1cm} (19)

for the aging law, and

$$\theta_{n+1}^{*} = \frac{L}{\delta_n} \exp \left( -\frac{\delta_n \Delta t}{L} \right).$$  \hspace{1cm} (20)

for the slip law. This approach for updating the state variable is different from the one in Lapusta et al. [2000]. We compare the state-variable updating schemes in section 3.

5. Find the first prediction of slip velocity, $\delta_{n+1}^{*}$, by equating the magnitude of shear stress in (11) and strength in (15). The directions of shear traction vector $T_{n+1}$ and slip velocity vector $\delta_{n+1}^{*}$ have to coincide. From (11), the stick traction $T_{n+1}$ has the same direction because the fault impedance matrix $Z$ is isotropic (appendix A). By projecting (11) onto that direction and equating the shear stress magnitude with frictional strength, we obtain the following
relation:
\[ T_{n+1} = \tilde{T}_{n+1} - Z_n \delta_n = \psi(\delta_n, \theta_n) , \]
where \( T \) and \( \tilde{T} \) denote the magnitudes of \( T \) and \( \tilde{T} \), respectively. We find \( \delta_{n+1} \) using the Newton-Raphson search with \( \delta_n \) as the first guess. Once \( \delta_{n+1} \) are obtained, the traction \( T_{n+1} \) can be readily found.

6. Calculate the final prediction of state variable, \( \theta_{n+1}^* \), at the \((n + 1)\)th time step by replacing \( \delta_n \) in equation (19) or (20) with \((\delta_n + \delta_{n+1})/2\).

7. Find the final predictions \( \delta_{n+1}^* \) and \( T_{n+1}^* \) by repeating step 5 with \( \theta_{n+1}^* \) instead of \( \theta_{n+1} \).

8. Declare the value of \( T_{n+1}^* \) to be equal to the predictions with the superscript double asterisks. Using the directional cosines constructed from the components of \( T_{n+1} \), we obtain the components of \( T_{n+1}^* \) and relative traction \( \tau_{n+1} \).

9. Solve for acceleration of the entire medium:
\[ \ddot{u}_{n+1} = M^{-1}[ -Ku_{n+1} + B \tau_{n+1}] . \]

10. Complete the update of \( \ddot{u}_{n+1} \) by adding the term containing \( \ddot{u}_{n+1} \):
\[ \dddot{u}_{n+1} = \dddot{u}_{n+1} + \frac{1}{2} \Delta t \ddot{u}_{n+1} . \]

This scheme includes two iterations for the update of the state variable. Its accuracy, for a given space grid, is comparable to that of BIM, as discussed in section 3. Note that if the second iteration in the state-variable update is omitted, the accuracy significantly decreases in comparison to BIM which also includes two iterations for the update of the state variable.

### 3. Comparison of numerical results obtained with 2D SEM and 2D BIM

#### 3.1. 2D anti-plane problem and comparison criteria

To assess the accuracy of numerical results based on the developed SEM approach, we have conducted detailed comparison of simulation results obtained using SEM and BIM. For simplicity and efficiency, we set up an anti-plane (2D) test problem. The BIM model used for comparison is based on the BIM spectral formulation of Lapusta et al. [2000]. Figure 2 illustrates the geometry of the anti-plane SEM and BIM models. In SEM, a 15 km by 45 km rectangular domain is used, with four boundaries. The SEM model domain is large enough to avoid any wave reflections from the boundaries during the simulated time. The domain is replicated using periodic boundary conditions on both sides of the domain (Figure 2). The fault boundary obeys rate-and-state (RS) friction with the aging law of state variable evolution. By symmetry consideration, the medium across the fault boundary has equal and opposite motion. In the analogous BIM model, wave propagation is analytically accounted for by boundary-integral expressions. The fault in the BIM model is repeated periodically, as in the SEM model.

The parameters used in the simulations are listed in Table 1, and the distribution of initial shear stress on the fault is shown in Figure 4A. We make our test problem similar to the SCEC code validation of dynamic rupture (Harris et al., 2004) and the study of Day et al. (2005), in terms of bulk properties and cohesive-zone properties, but we use RS friction and consider a 2D scenario. Within the 3-km nucleation region, we use an integer number of spectral elements for SEM and an odd number of computational cells for BIM. We select the polynomial degree to be 4 in SEM throughout the comparison.

\( ^a \) The value within the rupture domain (Figure 4) is given.

\( ^b \) The values in the region of constant \((a - b)\) in the velocity-weakening area (Figure 7) are given.

At the nucleation patch in the center of the fault, slip velocity increases abruptly due to the difference between the initial shear stress imposed and initial shear strength given by the RS friction. (Note that the initial bulk particle velocity is uniform and equal to half of initial slip velocity on the fault outside the nucleation patch.) The resulting dynamic rupture propagates bilaterally from the nucleation patch. On the RS fault, friction strength is not known in advance as it depends on the current values of slip velocity and state variable. The RS parameters we use (Table 1) result in effective slip weakening similar to the LSW friction of the SCEC code validation (Figure 4B).

To quantify differences between solutions, we use a quantity analogous to the rupture arrival time. For problems
In the SCEC code validation with spontaneous dynamic rupture, the rupture arrival time has been shown to be a sensitive indicator of numerical precision that reflects the nonlinearity of the problem. This quantity is more convenient for RS faults as it does not require choosing a particular value of slip-velocity threshold and can be used in a wider context, for example, for comparing rupture arrival times approximately follow a power law in the average node spacing, with the estimated exponents of 1.85 for SEM and 1.93 for BIM. The estimated cohesive-zone size \( \Lambda \) averaged over the comparison domain is 0.21 km, and the numerical accuracy depends on the cohesive-zone resolution \( N_c \) consistently with the study by Day et al. [2005]. The results show that the highest-resolution solutions, convergence rates, and errors for both SEM and BIM are nearly identical, validating our new model algorithm.

3.3. Evaluation of state-variable updating schemes

The results in section 3.2 are obtained using the state-variable updating scheme (19). An alternative way of updating the state variable is to use the following relations in the updating scheme (section 2.3):

\[
\theta_{n+1}^* = \theta_n + \Delta t \delta \quad \text{at step 4,}
\]

\[
\theta_{n+1}^{**} = \theta_n + \frac{\Delta t}{2} (\delta \theta_n + \delta \theta_{n+1}) \quad \text{at step 6,}
\]

where \( \delta \theta_n \) is obtained from the state-variable evolution laws (13) or (14) with \( \delta = \delta_n \) and \( \theta = \theta_n \). This approach was...
constant slip velocity, one would expect the state-variable updating scheme (24) to be less accurate. We verify this expectation by numerical simulations (Figure 3B, C). While the two updating schemes are comparable for fine discretizations \((N_e \geq 2)\), the errors for the updating scheme (24) are higher in the case of coarser discretizations \((N_e \lesssim 2)\), for both SEM and BIM. The error difference for coarser discretizations may be important in 3D simulations, which tend to require marginal discretizations due to their demand on computational resources.

3.4. Comparison of simulations with linear slip-weakening (LSW) and rate-and-state (RS) friction

LSW friction laws are widely used to simulate dynamic rupture. Several dynamic rupture codes for LSW faults have been compared in the SCEC code validation [Harris et al., 2004]. LSW laws incorporate discontinuities in derivatives, such as the abrupt change from weakening to a constant dynamic friction level. RS laws, on the contrary, are smooth. Hence, it is reasonable to hypothesize that RS laws would lead to simulations with better numerical accuracy than LSW laws. Since the aging form of RS laws can match the overall shape of LSW laws quite well, we can use our simulations to test that conjecture. We use the same LSW friction as in the SCEC code comparison, and the parameters of RS friction are chosen to match that LSW friction during dynamic rupture (Figure 4).

Figure 5A shows that the two laws result in SEM simulations with comparable accuracy. However, there are important differences. For the node spacing larger than \(\sim 0.1\) km, the errors of solutions with LSW friction are 33\% higher on average than those with the aging law of RS friction. Hence, as expected, RS friction results in smaller errors for the same node spacing. Even though the computational time for the same node spacing is larger for RS friction than LSW friction, one can obtain the same accuracy using a coarser node spacing in the calculations with RS friction, actually reducing the computational time in comparison with LSW. To illustrate this point, we consider RMS difference in PSV arrival time over the domain \(8.5\) km \(\leq x \leq 9.0\) km, where the errors would be expected to be higher than for smaller \(x\) (Figure 5A inset). LSW simulation with \(\Delta x = 0.107\) km and RS simulation with \(\Delta x = 0.125\) km have comparable error of about 1\%. For the node spacing of 0.107 km, the CPU time is 1.35 times longer in the calculation with RS friction than in that with LSW friction. However, the CPU time and memory in the RS calculation with the node spacing of 0.107 km is 1.53 and 1.36 times larger, respectively, than the one with 0.125 km. Hence, RS calculation with \(\Delta x = 0.125\) km takes 12\% smaller CPU time and 36\% smaller memory than the LSW calculation with \(\Delta x = 0.107\) km that has comparable accuracy. This illustrates that the computational cost with respect to a given accuracy of a solution is smaller in calculations with RS friction than in those with LSW friction. Note that the differences in CPU time and memory become even larger for 3D computations, as the differences increase with the number of the node points.
and prevent further reduction of errors for finer discretizations. Such numerical oscillations are appreciably smaller in simulations with RS friction than in those with LSW friction, as Figure 5B shows for the node spacing of 0.036 km. The oscillatory slip velocity near the peak in the LSW simulation results in much higher errors for finer discretizations (Figure 5B). Note that numerical damping in the form of Kelvin-Voigt viscosity is often used to suppress numerical noise for the calculations with LSW friction [e.g., Day et al., 2005]. Our experience with using damping indicates that it also results in slower rupture speed (longer PSV arrival time), which decreases the convergence rate.

We quantify the degree of smoothness of the solutions obtained using the two friction laws by comparing the spectra of slip velocity (Figure 5C). The spectra differ for high frequencies ($f > 20$ Hz). While that frequency range cannot be resolved by inversions of seismological data and it is beyond the frequency band relevant for most engineering applications, it reveals important differences in the behavior of the two solutions. The decay of high frequencies ($20$ Hz $\lesssim f \lesssim 100$ Hz) for the simulation with RS friction is approximately proportional to $f^{-5/2}$, which is faster than the $f^{-3/2}$ decay for the simulation with LSW friction. Hence slip velocity at the onset of sliding for RS and LSW friction are proportional to $t^{3/2}$ and $t^{1/2}$, respectively, and the corresponding slip acceleration is proportional to $t^{1/2}$ and $t^{-1/2}$. This behavior of the numerical solutions indicates that, in the corresponding continuum solutions, slip acceleration at the onset of sliding is infinite, consistently with the finding of Ida [1973], and abruptly jumps from zero, whereas slip acceleration for RS friction is finite and smoothly changes from zero. The discontinuity in the continuum solution with LSW friction limits the quality of the corresponding numerical solutions. That is why the model with RS friction results in numerical solutions with smaller oscillations and has better convergence than that with LSW friction (Figure 5A, B).

We conclude that, for a given accuracy of solutions, the aging form of RS law leads to more stable and accurate simulations than LSW law, while producing savings in computational time and memory.

3.5. Simulations with the slip law of state-variable evolution

In addition to the aging law considered so far, other formulations of the state-variable evolution have been proposed, including the slip law, the composite law, and laws with more than one state variable [Ruina, 1983; Rice and Ruina, 1983; Gu et al., 1984; Kato and Tullis, 2001]. Several recent nucleation studies [Kato and Tullis, 2001; Rubin and Ampuero, 2005; Ampuero and Rubin, 2008] found notable differences between models with different state-variable evolution laws. Which formulations most adequately represent laboratory experiments is a question of active current research [e.g., Bayart et al., 2006].

Figure 6A shows that the errors of SEM solutions with the slip law are much higher than those with the aging law, for the same parameters. In comparison with the aging law, the slip law requires much higher numerical resolution to establish the same order of accuracy. This is because the effective slip-weakening rate (i.e. the rate of stress decrease with slip) is variable for the slip law, with the maximum effective slip-weakening rate larger in simulations with the slip law than with the aging law for the same RS parameters (Figure 6B) by a logarithmic factor of peak slip velocity [Ampuero and Rubin, 2008]. In our test problem, when the value of the characteristic slip $L$ in the slip law is increased eight times, the maximum effective slip-weakening rate becomes approximately equal for both laws in this particular model, and the errors in simulations with the slip law (Figure 6A) become comparable to the errors in the simulations

![Figure 5.](image-url)
with the aging law (Figure 3B). These results suggest that errors are controlled by the resolution of the maximum effective slip-weakening rate. Note that this is consistent with the notion that the resolution of cohesive zone controls errors for calculations with LSW friction and the aging law of RS friction. In LSW friction, effective slip-weakening rate at the rupture front is constant, and the cohesive-zone size reflects that rate. The aging law results in slip-dependent behavior close to that of LSW friction (Figure 6B).

4. Effect of velocity-strengthening fault friction at shallow depths on dynamic rupture

We use the SEM for rate-and-state faults developed in section 2 and validated in section 3 to investigate the effect of different fault rheologies on dynamic rupture in a 3D fault model. The fault is governed by the aging form of RS friction, with relatively uniform pre-stress. We consider two dynamic rupture scenarios on a vertical strike-slip fault embedded into an elastic half-space: Case 1 with velocity-weakening friction extending up to the free surface, and Case 2 with a shallow 3-km velocity-strengthening region next to the free surface (Figure 7). Case 2 is motivated by the inferred existence of a velocity-strengthening fault rheology at shallow depths as described in section 1. Absorbing conditions [Clayton and Engquist, 1977] are used on all boundaries of the SEM model except the free surface and the fault boundary, to simulate a semi-infinite elastic half-space.

Figures 7 and 8 illustrate parameters and initial conditions for the SEM model. The effective normal stress, \( \sigma = \min[1.0 + 16.2z, 80.0] \text{ MPa} \), where \( z \) is in kilometers, increases with depth due to the difference of overburden minus hydrostatic pore pressure and becomes constant (80.0

---

Figure 6. (A) Errors for SEM solutions with the slip law of state-variable evolution. Blue circles correspond to the errors for SEM calculations with the parameters of Table 1. Green stars correspond to the errors for SEM calculations with eight times larger characteristic slip \( L \). The overall errors for the slip law with eight times larger \( L \) is comparable to that of the aging law shown in panel B of Figure 3. (B) Effective slip dependence of the friction coefficient at \( x = 9.0 \text{ km} \) for the highest-resolution simulations with the aging law, the slip law, and the slip law with eight times larger \( L \). The squares show the values of stress and slip at the PSV arrival time at \( x = 9.0 \text{ km} \).

Figure 7. A 3D model of a vertical strike-slip fault embedded into an elastic half space. Two cases with different fault rheologies are considered, with and without shallow velocity-strengthening patch. At the horizontal transitions from velocity-weakening to velocity-strengthening properties (\( x = -10 \text{ km} \) and \( x = 30 \text{ km} \)), the value of \( a \) stays constant and the value of \( (a - b) \) abruptly changes from -0.004 (velocity weakening) to 0.004 (velocity strengthening). The depth dependence of \( a \) and \( (a - b) \) within the region \(-10 \text{ km} < x < 30 \text{ km}\) is shown in Figure 8.
ical plate loading rates of 10\textsuperscript{10} m/s. Starting at time t = 0, dynamic rupture is initiated by imposing a rapid but smooth time-dependent variation of the horizontal shear traction in a circular patch (E. Dunham, personal communication; Rojas et al. [2007]; appendix B). This initiation procedure results in fast but gradual variations in slip velocity, producing more stable numerical results for lower numerical resolutions in comparison to the more abrupt initiation procedure (in the form of an overstressed patch of higher initial stress) of section 2. The difference between the two procedures is especially important in 3D problems, which are expensive computationally.

Dynamic ruptures in the two cases are compared in Figures 9-12. Each simulation has an average node spacing of 0.050 km and takes 5 hours with 150 processors on Caltech supercomputer, CITerra. Figure 9 gives snapshots of the strike-parallel component of slip velocity every 2 seconds for Case 1 (top) and Case 2 (bottom). The rupture initiates at the nucleation patch and then spontaneously propagates until it encounters velocity-strengthening regions at the 15-km depth and at lateral distances of −10, 30 km, where slip gradually terminates. The resulting slip dependence of the RS simulation at the fault location (x, z) = (15 km, −7.5 km) is shown in Figure 8C.

4.1. Suppression of supershear rupture near the free surface

Significant differences between the two cases start to arise when the rupture reaches the velocity-strengthening patch next to the free surface. In the absence of the shallow velocity-strengthening patch (Case 1), the rupture front next to the free surface propagates with a supershear speed (Figure 9). This supershear rupture propagation near the free surface has been observed in simulations with LSW faults ([S. Day, personal communication; Aagaard et al. [2001]). In the presence of the shallow velocity-strengthening patch (Case 2), the supershear rupture propagation near the free surface is suppressed (Figure 9). This is consistent with the fact that supershear rupture propagation near the free surface has not been commonly reported in large crustal earthquakes. Our results indicate that velocity-strengthening friction at shallow depths may account for, or at least contribute to, the lack of universal supershear rupture near the free surface. Other factors might contribute to suppression of supershear propagation at the free surface, such as a potential increase in breakdown work close to the free surface due to more distributed shear at low normal stresses or lower initial shear stress than assumed in this work.

Figure 10 shows particle-velocity seismograms on the free surface, 2.0 km away from the fault trace. We see that the arrival phase in the waveforms (a solid black line) has a speed higher than the shear wave speed (V\text{S}). The differences in waveforms for the two cases are significant due to the combination of two effects in Case 1: high slip velocity on the fault near the free surface and the supershear phase. The differences indicate that it might be possible to infer the existence of shallow velocity-strengthening patches from seismic observations.

4.2. Smaller final slip throughout the fault

The shallow velocity-strengthening patch in Case 2 causes an appreciable slip reduction over the entire fault (Figure 11). The existence of the shallow velocity-strengthening patch suppresses the slip due to the combination of two effects. The first one is that the healing phase created at the shallow rheological transition gradually ceases the slip at depth. The second effect is that the rupture reflected from the free surface in Case 1 induces further slip at depths, whereas in Case 2, the effect of the reflected rupture decreases due to the suppressed slip in the velocity-strengthening patch at shallow depths. Thus, the total amount of slip at depth is smaller in Case 2 than in Case 1 (i.e., 25% smaller at the receiver in Figure 11). The difference in final slip between Case 1 and Case 2 is largest next
to the free surface. The resulting profile of slip with depth (Figure 11) indicates shallow coseismic slip deficit, which is qualitatively consistent with observations [Fialko et al., 2005]. Note that these two rupture scenarios yield comparable moment magnitudes; $M_w = 7.1$ in Case 1 and 7.0 in Case 2.

The slip reduction corresponds to smaller stress drop. The values of depth-averaged (from 0 km to 15 km) static stress drop for Case 1 and 2 (Figure 11) are 4.9 MPa and 3.5 MPa, respectively. Note that stress drop within the shallow velocity-strengthening patch is negative, that is, shear stress increases after the earthquake. Another mechanism that can contribute to negative stress drop at shallow depths is low initial stress in low-rigidity shallow materials resulting from uniform tectonic strain [Rybicki and Yamashita, 1998].

4.3. Faster decrease of slip velocity behind the rupture front: implications for the rise time

One of the important source parameters inferred by seismic inversions is the rise time $T_s$ (i.e., slip duration at a point on the fault). Let us consider the rise time for Cases 1 and 2. Figure 12A shows the evolution of slip velocity at the middle of the seismogenic depth (7.5 km depth) at the distance of 15 km from the center of the nucleation patch (the inverted triangle in Figure 9). This representative profile has a strong rupture front followed by gradually decreasing weak “tail”, for both Cases 1 and 2. Such slip velocity profile is commonly referred to as “crack-like”, as there is no self-healing behind the rupture front. However, slip velocity in the “tail” is rather small and slowly-varying compared to the

Figure 9. Snapshots of horizontal slip velocity (m/s) on the fault every 2 seconds for Case 1 (top) and Case 2 (bottom). White lines on two snapshots represent the boundary between velocity-weakening and velocity-strengthening regions. Slip velocity and slip at the location of an inverted triangle are plotted in Figure 12. Note that only a part of the fault close to the velocity-weakening region is shown.
rupture front. The rise time that seismic inversions would determine for such rupture should depend on the inversion method, the amount and quality of available seismic data, and other factors, and determining that “seismic” estimate of the rise time is beyond the scope of this study. To obtain some simple estimates, we consider here slip durations with slip velocities larger than a given cut-off value (Figure 12B). Note that the resulting slip durations are generally lower for Case 2 which contains the shallow velocity-strengthening region.

We compare these slip durations with the study by Heaton [1990] which demonstrated that the rise time $T_s$ in

Figure 11. Final slip over the fault and depth profiles of slip and stress drop along the dashed lines for Case 1 (top row) and Case 2 (bottom row). Slip in Case 2 is reduced throughout the fault. The shallow velocity-strengthening patch results in negative stress drop (or stress increase).
5. Effect of velocity-strengthening friction at shallow depths on ground-motion amplification due to a layered bulk structure

In this section, we investigate how low-velocity bulk layers at shallow depths, in combination with different fault rheologies, affect the ground motion. Figure 13A illustrates elastic parameters used for the layered bulk structure; two low-velocity layers above 5-km depth are added to the homogenous case used in section 4. This layered bulk model approximately corresponds to the 1D Parkfield bulk structure used in the study by Custódio et al. [2005]. Uniform bulk attenuation is accommodated by the approach of Ko-
In the absence of attenuation or for weaker attenuation ($Q_s \gtrsim 40$), the amplitude of the Rayleigh waves becomes larger than the amplitude of body waves at the distance of several kilometers from the fault trace and remains high over a wide range of the off-fault distances. However, such high-frequency Rayleigh waves have not yet been observed in strong-motion records (Heaton, personal communication). One explanation for the absence of the high-frequency Rayleigh waves is that they scatter by more complex bulk structure than the idealized layered bulk assumed in our simulations (Heaton, personal communication). We show that a shallow velocity-strengthening fault region can provide an alternative explanation, since high-frequency Rayleigh waves do not form in the case with velocity-strengthening fault friction at shallow depths (Figure 14), which suppresses slip velocity near the free surface.

6. Conclusions

We have developed an algorithm for simulating dynamic rupture on rate-and-state (RS) faults in the context of 2D and 3D SEM models. Our SEM test results have accuracy comparable to that of BIM over a wide range of node spacings. We have also demonstrated that the computational cost with respect to a given accuracy of a solution is smaller in calculations with the aging form of RS friction than with linear slip-weakening friction. Simulations with the slip form of RS friction require much higher numerical resolution than those with the aging form due to the higher maximum effective slip-weakening rate at the rupture front than for the aging law, for the same rate-and-state parameters. As a result, we have found that solution errors in dynamic rupture problems are controlled by the resolution of the maximum effective slip-weakening rate at the propagating rupture front.
the presence of velocity-strengthening fault friction at shallow depths significantly affects dynamic rupture. A shallow velocity-strengthening region suppresses supershear propagation near the free surface, which could explain the lack of strengthening properties of the shallow layer can be adjusted to completely prevent the rupture from propagating to the free surface. A shallow velocity-strengthening region results in faster decrease of slip at the tail of propagating rupture at seismogenic depths than in the case without such region, creating shorter effective rise times. The amplification of ground motion due to low-velocity elastic structure such as aseismic transients and afterslip, but also for dynamic rupture and the associated seismic hazard.

Note that earthquake rupture in this work is nucleated either abruptly or relatively rapidly, as common in simulations of a single earthquake [e.g., Harris et al., 2004; Day et al., 2005; Rojas et al., 2007]. While the conclusions in this study should not depend on the nucleation procedure, a number of earthquake problems require the ability to simulate more gradual nucleation under slow tectonic loading, post-seismic and other aseismic slip, and sequences of simulated earthquakes, while still accounting for inertial effects during simulated earthquakes. For simple fault geometries and a uniform elastic medium, this has been accomplished by BIM approaches [e.g., Lapusta et al., 2000; Liu and Lapusta, 2006]. To allow for more flexibility in fault geometry and bulk properties in long-term simulations of fault slip, we are developing a combined SEM [Kaneko et al., 2007] that merges a quasi-static SEM with the fully dynamic SEM presented in this work.

There is growing evidence that friction is much lower at seismic slip velocities than RS friction laws predict [e.g., Di Toro et al., 2003; Rice, 2006; Han et al., 2007; Lu et al., 2007, and references therein]. The presented SEM framework can be extended to include dynamic weakening mechanisms such as pore pressurization and flash heating [Rice, 2006, and references therein], which can be combined with RS friction to account for a wide range of seismic and aseismic slip velocities. SEM can incorporate complex 3D geometrical effects such as 3D basins and seismic Moho [Casarotti et al., 2007]. Furthermore, it can be extended to include non-planar fault geometries and heterogeneous and/or non-elastic bulk properties, factors that are important for understanding fault behavior, and in particular large earthquakes.

Appendix A: Fault boundary matrix

The fault surface \( \Gamma \) consists of quadrilateral elements \( \Gamma_\varepsilon \) inherited from hexahedral elements lying on the two sides \( \Gamma_\pm \) of the fault. The matrix \( B \) in (1) is a sparse rectangular matrix obtained by assembling the contributions \( B_\varepsilon \) from each of the fault boundary elements \( \Gamma_\varepsilon \) that are the same for the three components of traction. The term of \( B \), associated with the GLL node with local indices \( (i, j) \) in \( \Gamma_\varepsilon \in \Gamma_\pm \) is

\[
B_{ij \pm}^{\varepsilon} = \pm \omega_k \omega_j j_{ij}^{\varepsilon},
\]

where \( \omega_k \) denote the weights associated with the GLL integration quadrature and

\[
J_{ij}^{\varepsilon} = \left| \frac{\partial \mathbf{x}}{\partial \xi} \times \frac{\partial \mathbf{x}}{\partial \eta} \right| (\xi, \eta)
\]

is the Jacobian of the coordinate transformation from \( \mathbf{x} \in \Gamma_\varepsilon \) to \( \xi = (\xi, \eta) \in [-1, 1]^2 \).

The outward normal vector of the fault boundary \( \Gamma^+ \) is obtained by

\[
n(\xi, \eta) = \frac{1}{|J_\varepsilon|} \frac{\partial \mathbf{x}}{\partial \xi} \times \frac{\partial \mathbf{x}}{\partial \eta}.
\]

Appendix B: Rupture initiation procedure

To nucleate dynamic rupture in a short period of time, we need to abruptly increase slip velocity from values below typical plate loading rate (~10^{-12} m/s) to coseismic ones (~1 m/s). To achieve this numerically, we use a perturbation of shear stress that smoothly grows from zero to its maximum amplitude \( \Delta \tau_{\varepsilon} \) over a finite time interval \( T \), and is confined to a finite circular region of the fault of radius \( R \). Following the approach used in Rojas et al. [2007] and in

![Figure 14](image-url)
the 2008 SCEC code validation, we apply a horizontal shear traction perturbation of the form:

$$\Delta \tau(x, z, t) = \Delta \tau_0 F\left(\sqrt{(x - x_0)^2 + (z - z_0)^2}G(t)\right)$$ \hspace{1cm} (B1)$$

where

$$F(r) = \begin{cases} \exp\left[\left(\frac{r^2}{R^2} - 1\right)\right] & \text{if } r < R, \\
0 & \text{if } r \geq R, \end{cases}$$ \hspace{1cm} (B2)$$

and

$$G(t) = \begin{cases} \exp\left(\left(t - T\right)^2/\left(2T^2\right)\right) & \text{if } 0 < t < T, \\
1 & \text{if } t \geq T. \end{cases}$$ \hspace{1cm} (B3)$$

The perturbation is radially symmetric, with the radial distance away from the hypocenter along the fault given by $$r = \sqrt{(x - x_0)^2 + (z - z_0)^2}$$. We use $$R = 2.5$$ km, $$\Delta \tau_0 = 19.0$$ MPa, and $$T = 0.1$$ seconds.

Acknowledgments. The authors thank Tom Heaton, Qinya Liu, and Yi Liu for helpful discussions. The reviews by Eric Dunham, Gaetano Festa, and an anonymous reviewer helped us improve the manuscript. We thank Eric Dunham for providing us with the unpublished functional form of the rupture initial procedure. Nadia Lapusta gratefully acknowledges the support of the National Science Foundation (Grant EAR 0548277) and the Southern California Earthquake Center. SCEC is funded by NSF Cooperative Agreement EAR-0106924 and USGS Cooperative Agreement 02HQAG0008. The SCEC contribution number for this paper is xxxxx. Jean-Paul Ampuero is supported by SPICE, a Marie Curie Research and Training Network in the 6th Framework Program of the European Commission. This is ETH contribution xxxxx. The numerical simulations for this research were performed on Caltech Division of Geological and Planetary Sciences Dell cluster.
