The insensitivity of the Antarctic Circumpolar Current’s (ACC) prominent isopycnal slope to changes in wind stress is thought to stem from the action of mesoscale eddies that counterbalance the wind-driven Ekman overturning—a framework verified in zonally-symmetric circumpolar flows. Substantial zonal variations in eddy characteristics suggest that local dynamics may modify this balance along the path of the ACC.

Analysis of an eddy-resolving ocean GCM shows that the ACC can be broken into broad regions of weak eddy activity, where surface winds steepen isopycnals, and a small number of standing meanders across which the isopycnals relax. Meanders are coincident with sites of (i) strong eddy-induced modification of the mean flow and its vertical structure as measured by the divergence of the Eliassen Palm flux, and (ii) enhancement of deep eddy kinetic energy by up to two orders of magnitude over surrounding regions. Within meanders, the vorticity budget shows a balance between the advection of relative vorticity and horizontal divergence, providing a mechanism for the generation of strong vertical velocities and rapid changes in stratification. Temporal fluctuations in these diagnostics are correlated with variability in both the Eliassen Palm flux and bottom speed, implying a link to dissipative processes at the ocean floor. At larger scales, bottom pressure torque is spatially correlated with the barotropic advection of planetary vorticity, which links to variations in meander structure. From these results, we propose that “flexing” of standing meanders provides an alternative mechanism for reducing the sensitivity of the ACC’s baroclinicity to changes in forcing, separate from an ACC-wide change in transient eddy characteristics.
1. Introduction

A remarkable feature of Southern Ocean circulation models is that the prominent isopycnal slope $s$ that spans the ACC is relatively insensitive to changes in surface forcing. This behavior is explained through the interplay between surface wind forcing, the flow’s baroclinicity and the action of mesoscale eddies. Residual-mean models of the ACC focus on zonally-averaged properties and emphasize the competition between a wind-driven Eulerian overturning circulation and an eddy-induced bolus transport, summarized as a counteroverturning cell that relaxes isopycnals (see review by Marshall and Speer (2012), and references therein). Assuming a near cancellation between wind-driven and eddy overturning cells

$$s \approx \frac{\tau}{\rho_0 f K},$$

(1)

where $\tau$ is the surface wind stress, $\rho_0$ is a reference density, $f$ is the Coriolis frequency and $K$ is some estimate of the eddy buoyancy diffusivity. Note that the insensitivity of $s$ does not imply an insensitivity of the residual overturning circulation, which responds to both the amplitude and form of surface buoyancy forcing (Stewart et al. 2013). The insensitivity of the isopycnal slope to surface forcing implies an adjustment of $K$ to in changes in $\tau$, or an enhancement in eddy kinetic energy in response to a wind-driven increase in isopycnal tilt, a state sometimes referred to as “eddy saturation” (Hogg et al. 2008). Idealized, zonally-symmetric models provide support for the relative insensitivity of $s$ to changes in $\tau$ (Abernathey et al. 2011; Stewart and Thompson 2013). Hydrographic observations also suggest changes to isopycnal slope in the ACC have been minimal over recent decades (Böning et al. 2008).

An important feature missing from residual mean models is the representation of the ACC’s complex frontal structure (Hughes and Ash 2001; Marshall et al. 2006; Sokolov and Rintoul 2009). This complexity in the ACC’s frontal anatomy is complemented by a striking heterogeneity in eddy characteristics (Venaille et al. 2011; Dencausse et al. 2011; Zika et al.
2013a). Fu (2009), Lu and Speer (2010) and Sallée et al. (2011) all document an enhancement of EKE and eddy diffusivities in the lee of topography. Thompson and Sallée (2012), using passive particles advected by a satellite-derived surface velocity field, link these regions to sites of enhanced cross-front transport. Naveira Garabato et al. (2011) develop theoretical arguments, first discussed in Ferrari and Nikurashin (2010), to show that ACC jets suppress meridional transport, except in regions where jets interact with topography. Using a kinematic argument, they conjecture that the interaction of transient eddies with small-scale, non-parallel structure in the mean flow, associated with standing meanders, leads to a local intensification of eddy-induced mixing across the ACC jets.

The apparent disconnect between the ACC’s along-stream structure and zonally-averaged theories for overturning and stratification has parallels with atmospheric storm tracks (Chang et al. 2002; Bengtsson et al. 2006; Kaspi and Schneider 2011). Adapting these results directly to the ocean is complicated, however, by the dramatic reduction in the deformation radius, which results in a scale separation between meander and eddy length scales that does not occur in the atmosphere. This scale separation was inferred from a scaling analysis by Williams et al. (2007). Williams et al. (2007) also compare atmospheric and oceanic storm tracks and find significant along-stream structure in eddy vorticity fluxes, associated with major topographic features, that may both accelerate and decelerate jets.

An important consideration is how the ACC achieves the balance in (1) following a change in $\tau$. These dynamics were explored in a study by Meredith and Hogg (2006), in which satellite altimetry data points to an increase in the ACC’s eddy kinetic energy (EKE) following an intensification of the surface westerlies, as measured by the Southern Annular Mode (SAM). The EKE rise occurs with a lag of about two years, which the authors identify as the time required for baroclinic eddies to extract, via baroclinic instability, available potential energy created by wind-driven isopycnal tilting. Figure 1 revisits and extends the Meredith and Hogg (2006) analysis by calculating regional time series of EKE anomalies in the Southern Ocean, derived from satellite altimetry data between 1993 and
2010. Anomalies are defined as differences from the 18-year time-averaged EKE. Panel (a) shows time series of basin characteristics considered by Meredith and Hogg (2006), with the SAM index overlain. A spatial map, however, indicates that anomalies peak in discrete regions associated with persistent meanders (panel c). Isolating these features (dashed lines), produces more dramatic EKE variability (panel b), especially compared to similar-sized regions outside of meanders (dashed-dotted line). The extended time series shows that correlation with the global SAM index is tenuous. This result is consistent with Gille and Kelly (1996), who showed that the amplitude of the first EOF of Southern Ocean SSH variability does not have a circumpolar or even a basin-scale trend. More recently, Dufour et al. (2012) showed that the ACC’s transient eddy response to an increase in wind stress is not zonally uniform. Morrow et al. (2010) note that Southern Ocean variability may also respond to ENSO and other climate modes and provide evidence that local variations in wind stress can generate local EKE anomalies.

In this study, we attempt to link the observed insensitivity of the ACC’s isopycnal slope to the notable along-stream variability in ACC properties. Using a high-resolution, eddy-resolving ocean GCM, the OFES model described in section 2, we explore the following hypotheses:

i. Buoyancy surfaces undergo a persistent wind-driven steepening over long stretches of the ACC where eddy fluxes are weak. This steepening is counter-balanced by isopycnal relaxation across a small number of standing meanders.

ii. Deep eddy kinetic energy and bottom speeds are elevated in the meanders and are coupled to surface variability through vorticity dynamics.

iii. Fluctuations in meander size are dynamically related to processes that transfer momentum vertically in the water column, both eddy buoyancy fluxes and horizontal divergence, and modify the baroclinicity of the flow.

Together these results lead us to propose that a major component of the ACC’s response
to changes in surface forcing occurs through fluctuations, or flexing, of the ACC’s dominant standing meanders. This behavior has a negative feedback that contributes to the leading order wind-eddy balance expressed in (1).

Section 3 characterizes eddy properties across a small number of meanders, focusing on the vertical structure of the flow. Temporal variability in the size and structure of the meanders is also considered. Section 4 presents a discussion of this discrete view of ACC dynamics, and our conclusions appear in section 5. This study does not provide a complete picture of the complex role that standing meanders play in global properties of the ACC. In particular, the relative importance of relaxation by standing meanders and transient eddies remains to be quantified. However, the dynamics discussed below highlight the need to better understand variability in the ACC’s energetic standing meanders.

2. Model data and theory

a. Ocean General Circulation Model for the Earth Simulator (OFES)

This study focuses on the spatial and temporal variability of eddies and standing meanders, with particular attention on their vertical structure. Meanders arise from flow interactions with significant topographic features. Thus a realistic, high-resolution, primitive equation numerical model is best suited to obtain these diagnostics.

Improvements in Southern Ocean models have resulted in flows populated by many narrow, meandering small-scale jets and coherent mesoscale eddies (Hallberg and Gnanadesikan 2006; Mazloff et al. 2010). Here we use output from the 1/10° OFES model (Masumoto et al. 2004), with emphasis placed on the dynamics governing the model output, as opposed to an exact comparison with observations of the ACC. Statistical measures from OFES, such as the distribution and amplitude of EKE, are comparable to both satellite altimetry data and other GCMs (see Thompson et al. (2010)). The model includes 54 vertical levels of varying depths and realistic bathymetry. Snapshots of the temperature, salinity and velocity fields
are available every day for a period of 8 years following a 50-year spin-up. Due to the vast quantity of data, we analyze snapshots obtained every third day. Time series of daily and three-day sub-sampled velocity and vorticity fields have been visually inspected to ensure that high-frequency dynamics are not aliased. The model is forced with a climatological wind field, so we are unable to directly consider the response of the Southern Ocean to climatic perturbations in forcing.

b. Vorticity balance

ACC standing meanders are intricately related to the zonal transport, which is sufficiently strong that baroclinic Rossby waves are unable to travel westward (Hughes et al. 1998). This behavior has been linked to enhanced eddy diffusivities by Ferrari and Nikurashin (2010), amongst others. The strong mean flow also generates an equivalent barotropic velocity structure in which bottom form stress becomes critical for flow equilibration (Hughes and de Cuevas 2001). In regions where the wind stress is weak, the barotropic vorticity budget implies that meridional velocities, related to meanders, must be balanced by a bottom pressure torque, arising from a geostrophic flow across isobaths.

Previous efforts to ascertain the ACC vorticity budget include Hughes (2005), (hereafter H05) who presents a surface budget from altimetry data under the assumption of quasi-geostrophic dynamics. Chereskin et al. (2010) consider the vorticity balance from LADCP-derived velocity data in the eastern Pacific, while Firing et al. (2011) extend the vorticity balance in the vertical using a region in Drake Passage instrumented with CPIES (inverted echo sounders with bottom pressure and near-bottom velocity sensors). Here we focus on the vorticity budget and its variability in pronounced standing meanders. Quasi-geostrophy (QG) remains a good assumption since $\zeta/f \ll 1$ over most of the domain (not shown). From Gill (1982) the interior QG vorticity balance is

$$\frac{\partial \zeta}{\partial t} + \mathbf{u} \cdot \nabla \zeta + \beta v - f \frac{\partial w}{\partial z} = 0,$$

(2)
where $\zeta = v_x - u_y$ and $w_z = -(u_x + v_y)$ by continuity; subscripts indicate partial differentiation. Assuming steady state, H05 finds a spatial anti-correlation between the advection of planetary vorticity $\beta v$ and the advection of relative vorticity $\mathbf{u} \cdot \nabla \zeta$, which is, however, sensitive to the choice of smoothing of the mean dynamic topography. H05 argues that the balance between the advection of relative vorticity and advection of planetary vorticity implies that stationary Rossby waves are short and thus have a dominantly barotropic character. The divergence term is not calculated, but is assumed to be small. This balance between $\beta v$ and $\mathbf{u} \cdot \nabla \zeta$ holds predominantly outside of the large meanders. Using the OFES numerical output, we revisit this balance in the meanders (section 3c).

c. Eliassen-Palm flux

The distribution of eddy fluxes in the ACC is also of interest, since momentum input by surface winds is transferred downward, via eddy buoyancy fluxes or interfacial form stress (Johnson and Bryden 1989), before it is removed by bottom form stress across topographic features (Munk and Palmèn 1951; Olbers et al. 2004). We note that Ward and Hogg (2011), analyzing a five-layer primitive equation channel model, challenge this view by showing that a rapid response of the bottom form stress, following a change in surface wind forcing, results in both a downward (from the surface) and upward (from the bottom) propagating baroclinic adjustment of the flow via interfacial form stress. This vertical momentum transfer requires an understanding of interior potential vorticity fluxes encapsulated by the divergence of the Eliassen-Palm (EP) tensor, $\mathbf{E}$ (Plumb 1986). The distribution of $\mathbf{E}$ along the path of the ACC is not well documented.

In light of the zonal variability in eddy characteristics, we retain all six components of
the EP tensor $E = [E_1; E_2]$, where

$$E_1 = \left(\overline{w'v'} \right) i + \frac{1}{2} \left( \overline{v'^2 - w'^2 + \frac{b'^2}{N^2}} \right) j + \left( \frac{f_0}{N^2} \overline{w'v'} \right) k \quad (3)$$

$$E_2 = \frac{1}{2} \left( \overline{v'^2 - u'^2 - \frac{b'^2}{N^2}} \right) i - \left( \overline{w'v'} \right) j + \left( \frac{f_0}{N^2} \overline{v'v'} \right) k. \quad (4)$$

Overbars represent time averages, primed quantities are deviations from such averages and $i, j$ and $k$ are zonal, meridional and vertical unit vectors. Acceleration of the zonal and meridional mean flows occurs in regions of divergence of $E_2$ and $E_1$ respectively. The divergence of these fluxes are equivalent in a QG limit to the eddy fluxes of potential vorticity:

$$\overline{u'q'} = \nabla \cdot E_1 = \left(\overline{w'v'} \right)_x + \frac{1}{2} \left( \overline{v'^2 - w'^2 + \frac{b'^2}{N^2}} \right)_y + \left( \frac{f_0}{N^2} \overline{w'v'} \right)_z \quad (5)$$

$$\overline{v'q'} = \nabla \cdot E_2 = \frac{1}{2} \left( \overline{v'^2 - u'^2 - \frac{b'^2}{N^2}} \right)_x - \left( \overline{w'v'} \right)_y + \left( \frac{f_0}{N^2} \overline{v'v'} \right)_z, \quad (6)$$

In section 3b we are concerned with changes in the mean flow along the path of the meander. The eddy forcing of this along-stream mean flow is described by the cross-stream flux of QG potential vorticity, $\nabla \cdot \mathcal{E}$, defined by

$$\nabla \cdot \mathcal{E} \equiv [\nabla \cdot E_1; \nabla \cdot E_2] \cdot \mathbf{n}_\perp^T, \quad (7)$$

where $\mathbf{n}_\perp = (-\sin \theta, \cos \theta)$ is the unit vector perpendicular to the along-stream flow direction.

We show in section 3 that $\nabla \cdot \mathcal{E} \approx \partial \mathcal{E}^z / \partial z$, where

$$\mathcal{E}^z \equiv (k \cdot \mathbf{E}) \cdot \mathbf{n}_\perp^T. \quad (8)$$

3. Results: the intermittent ACC

a. Meanders and stratification

We first examine the evolution of the ACC’s stratification between energetic standing meanders and regions of predominantly zonal flow. This approach is motivated by observations (Smith et al. 2010) of significant modifications in the vertical structure of the ACC
across major topographic features, with a tendency toward barotropization of the mean flow as it navigates topography.

Altimetry (Fu et al. 2010) and models (Hallberg and Gnanadesikan 2006) identify ACC meanders as sites of enhanced EKE. Figure 2 confirms that this relationship holds in the OFES model (only eastern hemisphere shown for clarity). The upper panels show (left) mean KE and (right) EKE at 100 m. EKE here is a deviation from an eight-year time mean such that it contains variability from both the standing meanders and transient eddies. Regions of elevated EKE are isolated downstream of significant topographic features (Fu 2009). The lower panels show the subsurface distribution of these properties, at a depth of 2500 m. The subsurface distribution of EKE is not well constrained by observations. A black contour is drawn in panel (d) to indicate regions where both surface and sub-surface values of EKE are elevated. These sites are all coincident with standing meanders. One interpretation of this distribution, which we explore next, is that mesoscale eddies make a localized contribution to the wind-eddy balance in (1).

Figure 3 (upper panel) shows the bathymetry of the Southern Ocean from the OFES model; vertical lines delineate sub-regions considered in the lower panels. Panels (a) and (b) consider two distinct areas: the former (28°E to 38°E) is a narrow sector of the ACC characterized by high EKE and dominated by a standing meander centered at 30°E; the latter (100°E to 145°E) is a broader sector of nearly zonal flow with low EKE. The contours of \( \Delta \) in panels (a) and (b) indicate the change in potential density \( \sigma_0 \) between downstream (\( \phi_2 \)) and upstream (\( \phi_1 \)) longitudes,

\[
\Delta \equiv \sigma_0(\phi = \phi_2, \xi, z) - \sigma_0(\phi = \phi_1, \xi, z), \tag{9}
\]

where \( \phi \) is longitude, \( \xi \) is dynamic height and \( z \) is depth. The \( \sigma_0 \) surfaces are mapped into depth-dynamic height coordinates, referenced to 2000 m, to account for the meridional displacement of the ACC core. Arrows indicate the sense of isopycnal displacement at 1500 m for ease of interpretation. Panel (a) shows a shoaling of isopycnals on the equatorward flank of the ACC consistent with a relaxation in isopycnal tilt across the meander. In contrast,
Δ values of similar magnitude but with a sense indicative of a steepening of the isopycnals appear in panel (b).

Panels (c) and (d) show similar behavior in other regions of the ACC. In particular, there is steepening of isopycnals between 120°W and 70°W across the eastern Pacific sector of the ACC. The change in density across Drake Passage is more extreme, with the isolated region now spanning 20° of latitude (60°W to 40°W). Drake Passage is a more substantial disruption to the ACC, and accommodates multiple standing meanders. This region requires further attention than there is scope for here (see review in Meredith et al. (2011)).

The residual-mean framework assumes the ACC’s isopycnal slope arises from approximately equal contributions from the mean wind-driven and eddy-induced circulations. In a zonally-symmetric domain this balance applies locally at every longitude. Figures 2 and 3 show significant variability in eddy characteristics and stratification along the path of the ACC, whereas surface wind and buoyancy forcing are zonally symmetric to leading order (Large and Yeager 2009). Thus a picture arises in which the ACC is partitioned into regions of wind-driven steepening, compensated by localized isopycnal relaxation. While this is clearly a simplified view, it represents a significant departure from the local balance implied by zonally-symmetric theories of the ACC.

b. Meanders and vertical structure

We next consider the vertical structure of a typical standing meander; this feature, found at 30°E, corresponds to the rapid relaxation of density surfaces depicted in Figure 3.

Figure 4a shows the mean surface buoyancy, $b = g \rho_0^{-1} (\rho_0 - \rho)$, $\rho_0 = 1025 \text{ kg m}^{-3}$, of the meander. Upstream, the surface buoyancy contours are closely packed together, whereas immediately downstream of the meander the surface buoyancy gradient weakens, reflecting a change in subsurface density distributions (Figure 3a). The appropriate choice of coordinate system to track flow characteristics along the path of the meander is complicated (Viebahn and Eden 2012). The meander does not coincide with an individual surface buoyancy con-
tour, nor is it obvious whether surface properties, or properties at any single level, are the
correct framework in which to “follow” the meander. Instead, we select a meander envelope,
given by the 0.0045 and 0.0065 m s\(^{-2}\) surface buoyancy contours (panel a); properties are
averaged over the meridional extent of the envelope, e.g. a quantity \(\chi\) averaged along the
meander is given by
\[
\tilde{\chi}(\phi, t) = \frac{1}{d_\phi} \int_{\theta_1}^{\theta_2} \chi \, a \, d\theta,
\]
where \(\theta_1\) and \(\theta_2\) are the latitudes of the bounding contours, \(d_\phi\) is the meridional distance
between the contours and \(a\) is the Earth’s radius. These contours are arbitrary, and the
following results are not qualitatively dependent on the choice of contours.

Panel (b) shows EKE averaged within the meander envelope. The peak in eddy kinetic
energy corresponds with the crest of the meander with a striking two-order-of-magnitude
change across the meander. At depths greater than 1500 m, the transition is abrupt. The
increase and subsequent decay in deep EKE occurs over 15\(^\circ\) of longitude, or approximately
1000 km. Along-meander profiles of mean KE look similar to EKE (not shown). This deep
signature of EKE is important for two reasons: (i) it suggests an enhancement of subsurface
eddy-induced mixing, and (ii) it provides a mechanism to locally enhance bottom form stress,
if the velocities have a component directed across isobaths.

Further evidence for the enhancement of deep eddy-induced mixing is shown in panel (c),
which depicts potential vorticity, which is well approximated by
\[
PV = f_0 \frac{\partial}{\partial z} \left( \frac{b}{N^2} \right),
\]
averaged over the meander envelope. At depths in excess of 2000 m, a bolus of homogenized
PV appears concurrently with the break in the surface meander. This is further evidence
that deep EKE impacts the deep stratification.

As discussed in section 2c, acceleration of the along-stream mean flow via eddy-induced
fluxes is related to the divergence of the Eliassen-Palm flux, \(\nabla \cdot \mathcal{E}\). Figure 5 diagnoses the
full calculation of \(\nabla \cdot \mathcal{E}\) from (7) as well as the approximation \(\partial \mathcal{E}^z/\partial z\) (8) and the difference
of the two values. A striking feature is that the vertical flux of momentum is truly localized in the standing meander.

A recurrent pattern found in the ACC standing meanders entails a divergence of $\mathcal{E}^z$ upstream of the meander, and a deep convergence of $\mathcal{E}^z$ within or just downstream of the meander. This pattern is consistent with an acceleration of the jet leading into the meanders, which agrees with the acceleration found by Williams et al. (2007). This divergent band has a vertical structure, with greater values near the surface, that implies an along-stream increase in the baroclinicity of the flow. The band of convergence, on the other hand, occurs at the site of highest EKE and is associated with a broadening of the jet and a deceleration of the mean flow. The negative values of $\mathcal{E}^z$ here imply a downward flux of momentum. The divergence of $\mathcal{E}^z$ has a vertical structure with larger amplitudes in the upper water column, thus making the flow more barotropic. The sites of maximum divergence / convergence and the transition between them are marked by white dashed lines in each of the panels in Figures 4 and 5, for reference. Note that the convergence is displaced downstream of the meander center suggesting an advection of transient eddies between sites of generation and mean flow modification (Pierrehumbert 1984; Bischoff and Thompson 2014).

The distributions of these diagnostics across different standing meanders is remarkably similar. Figure 6 shows the (a) surface buoyancy, (b) EKE, (c) $\mathcal{E}^z$, (8) and (d) $\partial\mathcal{E}^z/\partial z$ of other prominent standing meanders found at 155°E and 145°W. The lower panels also present calculations of meander characteristics within a meander envelope, defined by the white contours in panel (a). In each meander, $\nabla \cdot \mathcal{E} \approx \partial \mathcal{E}^z/\partial z$. Again, below 2000 m EKE is elevated within narrow bands that coincide with the location of the meander, and the distribution of the eddy potential vorticity implies a deceleration and barotropization across the meander. Figures 5 and 6 show that in each meander the reduction in baroclinicity within the meander dominates the acceleration immediately upstream, leading to an overall barotropization of the flow in these regions.
c. Meanders and vorticity balance

From (2), the steady vorticity balance in the ocean interior implies a balance between the advection of total vorticity \((f + \zeta)\) and the divergence, or stretching, term \(-fw_z\). In the barotropic vorticity balance, an incomplete cancellation between components of the advection of total vorticity results in non-zero bottom velocities (Hughes and de Cuevas 2001). H05 calculated all three terms in the steady vorticity balance, (2), from altimetry data, but needed to apply a smoothing filter following each differentiation. This resulted in the dominant scale of the relative vorticity advection \(u \cdot \nabla \zeta\) (300 to 500 km) being comparable to meanders in the dynamic height field, and thus with the advection of planetary vorticity, \(\beta v\). Here, the 0.1°-resolution model OFES allows calculation of each term in the vorticity balance without the use of smoothing filters.

Figure 7 (a)–(c) shows an 8-year time average of the three terms in (2) for the standing meander at 155°E at 250 m depth. The advection of planetary vorticity (panel c) is the smoothest of the three terms, but is an order of magnitude smaller than the advection of relative vorticity and the divergence. The divergence and the advection of relative vorticity show smaller-scale variations and are spatially correlated. These terms also cancel to leading order with the residual having the same magnitude as the advection of planetary vorticity, but smaller spatial structure (not shown).

The balance between advection of relative vorticity and divergence dominates throughout most of the water column as seen in Figure 8, which shows the spatial correlation and linear regression coefficients of the different terms in the vorticity budget at various depths. The balance between \(u \cdot \nabla \zeta\) and \(-fw_z\) also holds in other major standing meanders, as shown in Figure 9 for meanders at 30°E and 150°W. The regression between these two fields in each meander is close to 1, which is similar to H05, although we also find that correlation and regression coefficients are sensitive to the introduction of smoothing.

Any individual snapshot of either \(fw_z\) or \(u \cdot \nabla \zeta\) shows considerably smaller scales than the time-averaged fields. These fields also vary coherently as the structure of the meander
changes, a process suggesting an important role for Rossby waves. From inspection, the two
terms are seen to have a strong correlation over short time scales. Figure 10a summarizes
this relationship by showing a time series of $|f w_z|$ (solid) and $|u \cdot \nabla \zeta|$ (dashed) averaged over
the region shown in Figure 7. The temporal correlation coefficient between these two time
series is 0.905 with no smoothing and increases to 0.956 when a two-month running mean
smoother is introduced. This strong temporal coherence is indicative of the small-spatial
scale agreement that occurs between these terms.

In contrast, the barotropic vorticity balance occurs over larger scales. Figure 7d shows the
8-year time mean bottom pressure torque within the same standing meander, and Figure 10b
shows the temporal evolution as described above. A relationship between bottom pressure
torque and meander amplitude might be expected since the leading order balance of the
barotropic vorticity budget is between bottom pressure torque and advection of planetary
vorticity (Hughes and de Cuevas 2001). In panel (b) we plot a rough estimate of the meander
amplitude, obtained from removing a linear approximation of the mean surface buoyancy
across the meander and plotting the root mean square amplitude of the buoyancy anomalies
over the eight-year period. The variability of the meander in the context of curvature is
explored in section 3d.

In summary, variability in the advection of relative vorticity, related to meander dynam-
ics, is linked to fluctuations in vertical velocities. This relationship is probed further by the
inclusion of a third curve in Figure 10a that shows a regional average of bottom speed (the
lower-most complete cell at each longitude and latitude) in the meander. Bottom speed,
which shows significant variations over the 8-year time series, is strongly correlated with
both the divergence (corr. coef. = 0.913) and the advection of relative vorticity (corr. coef.
= 0.892); these vorticity components are calculated at 250 m.
d. Meanders and time variability

The temporal covariance of terms in the vorticity balance motivates a consideration of how changes in the meander structure relate to eddy characteristics, and follows earlier studies of standing meanders by H05, Ochoa and Niiler (2007).

Scale separation between mesoscale eddies and the size of the meanders themselves is a distinguishing feature of ocean storm tracks (Williams et al. 2007). For example, in the vorticity budget, snapshots show a correlation between advection of relative vorticity and divergence at scales comparable to the deformation radius (\( \sim 20 \text{ km} \)), while the time-averaged balance and the barotropic vorticity balance is related to the meander scale (\( \sim 400 \text{ km} \)).

A comparable scale separation in time is less apparent, however. The upper panels of Figure 11 indicate changes to the structure of the standing meander at $155^\circ\text{E}$ over an 8-year time period. Panel (a) shows the 8-year time average of the buoyancy contours at 250 m depth for the region shown in Figure 7—the flow is equivalent barotropic and thus buoyancy contours have similar curvature at other depths. Panels (b) and (c) are 2-month means of buoyancy during periods of weak and strong curvature, respectively. As a measure of curvature, $C(b, t)$, the length of buoyancy contours within the range $-1 \times 10^{-3} < b < 5 \times 10^{-3}$ m s$^{-2}$ are calculated. In cases where multiple contours exist, due to coherent vortices, we select the maximum contour length. These lengths are calculated for each snapshot over 8 years and the resulting curvature time series, $\overline{C}_b(t)$, averaged over the buoyancy range $1 \times 10^{-3} < b < 2.5 \times 10^{-3}$ m s$^{-2}$, is given by the bold curve in panel (d). Here the time series is smoothed using a 2-month running mean; periods of weak and strong curvature shown in the upper panels are marked by the red dashed lines. $\overline{C}_b(t)$ is compared to fluctuations in the vorticity budget terms, revealing a strong temporal correlation, especially between months 20 and 90. This agreement depends on the choice of buoyancy contour, and becomes worse outside of the ACC’s core. Panel (e) shows the correlation coefficient between the divergence $-fw_z$ and curvature $C(b, t)$ time series for different values of $b$. Buoyancy contours with a correlation coefficient greater than 0.45 (dotted line) are given as bold curves in panels (a)
through (c), and explains our averaging choice for the bold curve in panel (d).

Finally, there is also a positive correlation between the time series of $C^b$ and meander-averaged EKE. The correlation coefficients for $C^b$ and EKE are 0.34 and 0.46, where the latter value has a 2-month running mean applied. Thus, on scales of a few months or longer, meander curvature and vorticity is also tied to the generation of mesoscale variability (EKE) and even submesoscale flows (strain generation and frontogenesis), which is essential to our proposed negative feedback discussed below.

4. Discussion

The existing framework for understanding the ACC’s equilibrated stratification (isopycnal slope) relies on a near balance between a mean and eddy overturning, where the latter is related to a zonally-averaged estimate of an eddy buoyancy diffusivity. Figures 2 and 3 suggest there is a gap between this idealized picture of the ACC and the true spatial distribution of eddy generation and fluxes. The largest EKE values cluster around regions where the curvature of buoyancy surfaces is large, and may not be adequately described by traditional eddy parameterizations, e.g. Gent and McWilliams (1990), Ferrari and Nikurashin (2010).

Lack of high resolution data has hampered previous studies of the ACC’s vorticity balance, especially in regions of strong meandering (H05, Chereskin et al. (2010)), with Firing et al. (2011) a notable exception. These studies focus largely on the barotropic vorticity balance and emphasize a balance between advection of relative vorticity and advection of planetary vorticity. Crucially, these studies only resolve features on the scale of the meanders themselves (300 to 500 km), while in the GCM data, the prominent spatial scales in the vorticity balance are on the order of a few tens of kilometers. It is only in the time average (Figure 7) that the structure of the standing meander is recovered. Through resolution of these scales, we find that at any given level the amplitude of the advection of relative vorticity and the divergence term are roughly an order of magnitude larger than the
advection of planetary vorticity, a result that is confirmed in an idealized 5 km resolution
MITgcm channel model with topography (Bischoff and Thompson 2014). The importance of
the divergence term throughout the water column (Figure 8) suggests a role for ageostrophic
vertical velocities in modifying the stratification across a standing meander. Ageostrophic
vertical circulations that occur during frontogenesis (Spall 1997) are likely to be important,
as Williams et al. (2007) have shown that meanders tend to be regions of frontogenesis¹.
Lateral eddy buoyancy fluxes also play a role in the equilibrated stratification.

These results point to variability in the structure and eddy characteristics of standing
meanders being critical to the global ACC structure. As discussed in detail in H05, standing
meanders arise from the arrest of barotropic Rossby waves by the mean flow. Neglecting
vertical and lateral shears, the arrested Rossby wave is expected to exhibit a single char-
acteristic wavelength. Waves with longer and shorter wavelengths will propagate upstream
and downstream, respectively. This approach suggests that long-term changes in the shape
or curvature (Figure 11) of standing meanders are representative of changes in the mean
flow. The consequences of these fluctuations are two-fold.

The first effect of the meander fluctuations is somewhat tenuous, but offers a potentially
new way of viewing the equilibration of the ACC. A clear signal in the diagnostics presented
here, and consistent with Ward and Hogg (2011), is that changes in surface wind forcing have
a rapid deep, or barotropic, response that modifies patterns of bottom form stress or bottom
pressure torque. At the ocean bottom, the pattern of these changes are related to the scale
of the standing meander, not the smaller scales that govern the interior baroclinic response.
An adjustment of the barotropic vorticity balance thus requires a change in the meander
structure. This may occur either through an increase in meander wavelength, consistent with
the expectation from the barotropic Rossby wave dispersion relation that a longer wave would
be arrested by a stronger zonal mean flow, or through an increase in meander amplitude

¹Snapshots of the Rossby number from the OFES model, defined as $\zeta/f$, intermittently show magnitudes
greater than 0.5 in regions of strong strain.
related to an adjustment of the barotropic planetary vorticity advection. This rapid bottom response is consistent with diagnosed transports in channel models with bathymetry following a step change in wind stress: the transport rapidly increases and then decays slowly to a new equilibrated value (Ward and Hogg (2011)). Regardless of mechanism, this adjustment of the meander necessitates the movement of the pressure field across $f/h$ contours, modifying bottom form stress in the meander. In the model, we find a correlation between enhanced meander curvature and increased bottom speed, and we suggest that an enhancement of bottom speed may be a mechanism for enhanced dissipation either through either through bottom friction, or more likely the generation of lee waves (which are not resolved in the OFES model). Mazloff et al. (2013) have also identified the importance of fluctuations in the position of buoyancy outcrops in the Southern Ocean, showing that a geostrophic component of the overturning circulation arises from these variations. Variability, or flexing, of key meanders will make an important contribution to this component.

The second effect is clearer and shows that meander curvature is linked to eddy characteristics in the standing meander region, diagnosed through either EKE or more complex diagnostics like the Okubo-Weiss parameter or eddy potential vorticity fluxes. The reason for this is not fully explained here, but is likely related to the enhanced instability of a non-zonal mean flow (Smith 2007; Boland et al. 2012). This increase in eddy fluxes, however, is directly related to enhanced eddy buoyancy fluxes and the vertical transfer of momentum.\footnote{Nearly stationary meanders are apparent throughout the ACC, but their association with enhanced EKE is limited to the main standing meander regions highlighted in this study.}

Thus, standing meanders are key sites where changes in surface momentum forcing can be communicated rapidly throughout the water column. Fluctuations between states of strong and weak curvature is reminiscent of the observed flipping between steered and zonal jets in idealized simulations by Thompson (2010) and may have some relation to the jet jumping of Chapman and Hogg (2013). An analysis of the Okubo-Weiss parameter (not shown) shows that meandering also enhances the strain fields, suggesting that meanders are regions
where eddies are not only generated, but also torn apart by strong lateral shears, potentially leading to elevated mixing (Naveira Garabato et al. 2011; Thompson and Sallée 2012).

While this study alone is insufficient to complete the full picture, we put forward a discrete view of the ACC, motivated by the enhanced variability in a small number of standing meanders (Figure 1). In this view, the equilibrated structure of the ACC is maintained by fluctuations in these standing meanders. The fluctuations are a combined response of arrested Rossby waves and the barotropic vorticity balance to changes in the mean flow. Figure 12 provides a diagram of this feedback mechanism. An intensification of surface westerlies steepens isopycnals and accelerates the ACC, especially upstream of meanders where EKE is relatively weak (panel a). The increased zonal transport of the ACC then results in a change in the Rossby waves that are arrested by the mean flow, specifically longer wavelengths; increases in curvature are also expected as the flow moves towards a new steady vorticity balance (panel b). Enhanced curvature leads to increased EKE and lateral eddy buoyancy fluxes, the latter being responsible for vertical momentum transport and adjustment of the baroclinic structure of the meander (panel c). Furthermore, the standing meander sites we identify are coincident with regions of enhanced conversion of geostrophic flow into internal lee waves, as identified in recent maps by Nikurashin and Ferrari (2011) and Scott et al. (2011) and observations by Waterman et al. (2013). Most importantly, this work offers a physical mechanism that resonates with recent findings (Dufour et al. 2012; Zika et al. 2013b) that local standing meanders may provide the strongest control over the ACC’s overturning. We acknowledge that a “meander-only” equilibration is likely an extreme view of the ACC and the relative importance of relaxation occurring in standing meanders and that by transient mesoscale eddies distributed throughout the ACC.

Using ship-based and Argo hydrographic data, Böning et al. (2008) show that the ACC’s mean isopycnal slope has changed little over the past two decades, despite significant changes in wind stress as measured by the SAM index. Eddy saturation was suggested as a potential explanation for this behavior. However, Munday et al. (2013) have argued that the relevant
time scale for the ACC to adjust in the classical residual overturning framework is on the order of many tens of decades, due to the equilibration of the large basins to the north of the Southern Ocean to a new stratification. The localized response to changes in surface forcing, through the adjustment of Rossby waves and curvature discussed here, may provide a mechanism for a faster mode of equilibration to wind forcing, especially if large isopycnal excursions are limited to narrow regions around standing meanders. Finally, much of the interest in understanding the ACC’s response to changes in wind stress is the potential for this mechanism to explain variations in the structure and rate of the meridional overturning circulation, through modification of isopycnal outcropping and surface buoyancy forcing, across major climatic transitions (Lynch-Stieglitz et al. 2007). It is worth noting that these standing meanders are determined by topography, and thus their location is likely to remain fixed over climatic time scales, while their structure may respond to changes in the strength of the ACC or in the spatial distribution of surface forcings. An interesting open question is the degree to which local variations in the wind stress impact Southern Ocean stratification and overturning (Zika et al. 2013b).

5. Conclusions

Spatial variations of the ACC’s EKE distribution reflects significant along-stream changes in the dynamics that set the Southern Ocean stratification. Broadly, anomalies from the zonally-averaged stratification of the ACC can be related to wide regions of isopycnal steepening where the wind-driven overturning out-competes the eddy-induced overturning. These regions are typically associated with near-zonal flows with established frontal jets. Eddy activity is enhanced within the standing meanders, where isopycnals relax dramatically. This enhancement of EKE, which may arise from the increased instability of the mean flow’s non-zonal orientation, has two consequences. The first is to increase the cross-stream buoyancy flux, whose vertical divergence is related to the vertical transport of along-stream momentum.
Enhancement in EKE is also linked to the enhancement of vertical stretching which balances the advection of relative vorticity in the vorticity budget. This balance holds specifically in the standing meanders and differs from previous analyses of the ACC vorticity balance.

While this balance holds over an 8-year time average of the model output, perhaps more intriguing is the high coherence between temporal fluctuations generated by internal variability and seasonal fluctuations in the climatological winds. Each of the terms in the vorticity balance shows a strong correlation with meander curvature. As the flow has an equivalent barotropic structure, this change in meander structure impacts the advection of planetary vorticity. Changes in the mean flow are also expected to modify the wavelength of arrested barotropic Rossby waves, while a change in meander amplitude is consistent with the flow adjusting towards a barotropic vorticity balance. The vorticity balance suggests that eddy-meander dynamics provide a negative feedback between changes in the ACC zonal transport, patterns of bottom form drag and eddy-induced vertical momentum fluxes responding to changes in meander curvature. This provides a mechanism by which eddy saturation of the ACC may arise. This mechanism is separate from, but potentially working in tandem with, relaxation by transient eddies.

Appreciation of the importance of standing meanders is found in some of the first studies that probed the dynamics of the ACC, e.g. (Stevens and Ivchenko 1997). Here, the emphasis is on transient fluctuations in the meander structure having a strong control over the equilibration of the ACC’s stratification. Our results have motivated a series of idealized numerical simulations (Bischoff and Thompson 2014) that confirm the importance of meander response to changes in surface forcing. While this approach presents a potentially more complicated view of the ACC, with an emphasis on local dynamics rather than zonal- or streamwise-averaged properties, it also points to key regions that are critical to our understanding of the Southern Ocean’s evolution over climatic time scales.

List of Figures

1 (a) Time series of EKE anomalies (cm² s⁻²) from 1993 to 2010, calculated from satellite altimetry data, for different regions (solid lines, panel c) of the Southern Ocean, cf. Meredith and Hogg (2006), Figure 1. Anomalies are the difference from the eighteen-year mean EKE in each region. (b) Time series of EKE anomalies for different standing meanders in the Southern Ocean (dashed lines, panel c) and for a region of similar size outside of standing meanders (dash-dotted line in panel c). The cyan curve in panels (a) and (b) shows the SAM index over this period. (c) EKE anomaly (cm² s⁻²) for 2000 through 2002. Boxes correspond to regional averages plotted in the upper panels.

2 Summary of the OFES model output. (a) Mean kinetic energy (MKE) of the ACC’s eastern hemisphere at a depth of 100 m. The 0.05 m² s⁻² contour is shown in white. (b) MKE of the ACC at 2500 m depth. (c) Mean eddy kinetic energy (EKE) at a depth of 100 m. The 0.05 m² s⁻² contour is included. (d) Mean EKE at 2500 m depth. An additional black contour indicates where the EKE at 2500 m is at least a tenth of the EKE at 2500 m. Regions in grey indicate bathymetry.

3 (Top) Depth (m) of the Southern Ocean in the OFES model. (Lower panels) Difference in potential density Δ (kg m⁻³) (9) as a function of depth and dynamic height, referenced to 2000 m, for the regions (a) 28°E to 30°E, (b) 100°E to 145°E, (c) 120°W to 70°W and (d) 60°W to 40°W. Dynamic height increases from south to north across the ACC. Arrows are provided to show the sense of downstream isopycnal adjustment at 1500 m depth.
(a) Surface buoyancy (m s$^{-2}$) in the Atlantic sector of the ACC. White curves indicate the 0.0045 and 0.0065 m s$^{-2}$ contours and provide an envelope for the meander at 30°E. (b) EKE (m$^2$ s$^{-2}$) along the path of the meander. Values represent a mean value integrated between the contours in the meridional direction; the scale is logarithmic. (c) Quasi-geostrophic potential vorticity (s$^{-1}$), defined in (11), integrated between the white contours in panel (a); the scale is logarithmic. Dashed lines are used to compare spatial variability in components of the Eliassen Palm tensor $E$ in Figure 5.

(a) Eddy forcing of the along-stream flow as diagnosed by the divergence of the Eliassen Palm vector $\nabla \cdot E$ (m s$^{-2}$) defined in (7). (b) Vertical divergence of the vertical component of the Eliassen Palm tensor, $\partial E^z / \partial z$ (m s$^{-2}$), (8). (c) The difference between panels (a) and (b).

Meander characteristics (left) at Macquarie Ridge and (right) over the Udintsev Fracture Zone. (a) Surface buoyancy (m s$^{-2}$) with contours (white) used to define an envelope of the meander. (b) Vertical profile of mean eddy kinetic energy (m$^2$ s$^{-2}$, logarithmic scale) along the path of the meander. Values are averaged between the contours in panel (a). (c) $E^z$ (m$^2$ s$^{-2}$), (8), averaged along the path of the meander; the zero contour is given in black. (d) The vertical divergence $\partial E^z / \partial z$ (m s$^{-2}$); this term is approximately equal to the cross-stream eddy potential vorticity flux.

(a)–(c) Eight year time average of terms in the vorticity balance (2) (units of $10^{-11}$ s$^{-2}$) for the standing meander at 150°E and 250 m depth: (a) divergence $-f w_z$, (b) relative vorticity advection $\mathbf{u} \cdot \nabla \zeta$, (c) planetary vorticity advection $\beta v$. (d) Bottom pressure torque within the meander (units of $10^{-5}$ N m$^{-3}$).

In all panels the gray contour indicates the 3500 m isobath; contours of the 4000 m (black) and 3000 m (light gray) isobaths are also included in panel (d).
(a) Spatial correlation coefficient and (b) linear regression coefficient for terms in the vorticity budget (2) as a function of depth for the standing meander at 155°E (Figure 7). Colors distinguish correlations/regressions between the different terms given in the legend in panel (b).

(Top) Eight year average of the (a) divergence $-fw_z$ and (b) advection of relative vorticity $u \cdot \nabla \zeta$ at 250 m at the standing meander near 30°E. (Bottom) Eight year average of the (c) divergence $-fw_z$ and (d) advection of relative vorticity $u \cdot \nabla \zeta$ at 250 m at the standing meander near 30°E. near 150°W. Units for all terms are $10^{-11}$ s$^{-2}$.

(a) Time series of the magnitudes of different terms in the vorticity balance (2) for the standing meander at 155°E in Figure 7 at 250 m depth. The spatial average of the absolute magnitude of each term is calculated. The mean is removed and the time series is normalized by the maximum value. Time series of the meander-averaged amplitudes of bottom speed and the meridional buoyancy flux at 250 m are also shown. The latter term is smoothed with a two-month running mean. (b) Time series of the meander-averaged amplitude of bottom pressure torque; the time series is normalized as in the upper panel. An estimate of the meander amplitude is also given (see text for description). These time series have been smoothed using a two-month running mean.
(Upper panels) Buoyancy contours at a depth of 250 m, (a) averaged over a period of eight years, (b) during a period of weak curvature in year 4 and (c) during a period of strong curvature. (d) Time series of curvature, $\mathcal{C}_b(t)$ (bold curve) as measured by the mean length of the bold buoyancy contours in the upper panels. The time series has the mean removed and is normalized by the maximum amplitude; the time series is then smoothed using a 30 day running mean. The time series of the terms in Figure 10, smoothed in the same way, are given in gray for reference. The red dashed lines indicate times of weak and strong curvature shown in panels (b) and (c). (e) Correlation coefficient between the divergence time series in panel (d) and curvature, $\mathcal{C}(b,t)$ for different buoyancy contours. The bold curves in the upper panels correspond to values of $b$ where the correlation coefficient is greater than 0.45.

Diagram of the negative feedback mechanism mediated by Southern Ocean standing meanders. Red curves and text indicate the departure from an initial state (gray curves) in response to an increase in surface wind stress. (a) Isopycnals steepen outside of regions of strong eddy kinetic energy, accelerating the ACC. (b) Increased zonal transport results in a re-equilibration of the standing meander due to arrest of Rossby waves with a different wavelength and change in amplitude due to a modified vorticity balance. (c) Increases in meander curvature enhance eddy kinetic energy, eddy buoyancy fluxes and vertical momentum transport, which changes the baroclinic structure of the meander and decelerates the mean flow. Reduction of the mean flow allows the Rossby wave to travel upstream and modify the stratification.
