An analytical expression for the bidirectional reflectance field of a vegetation canopy is derived from physical and geometrical considerations of the transfer of radiation through a porous medium. The reflectance pattern is shown to depend explicitly on the optical properties of the scatterers (for example, leaves), and on the structural parameters of the canopy, such as the statistical distribution of the orientation of these scatterers, the leaf area density, the size of the scatterers and their interspacing. This theory provides a simple and accurate way to understand the anisotropy of the radiation field over a vegetated surface. It can be useful for modeling applications (for example, the albedo is a by-product which can be numerically estimated), as well as for extracting some of the structural and physical properties of the surface. These applications are discussed in the accompanying paper (Pinty et al., this issue).

1. Introduction

Vast amounts of satellite remote sensing data on the state and evolution of the surface of the Earth have been accumulated over the last decade. NASA's projected Earth Observing System (EOS) will significantly increase the size of this data base, not only with additional data, but also with improved spatial and temporal coverage, and enhanced spectral resolution [NASA, 1988]. These developments provide unique opportunities for various scientific communities, but the potential utilization of these data to retrieve quantitative estimates of land surface properties is currently limited by various drawbacks inherent to remote sensing techniques. One such limitation lies in our inadequate understanding of the physical processes governing the transfer of radiation at the surface of the Earth. This translates into a lack of physically based models to describe such processes and to invert these data into useful information.

It is well known that natural continental surfaces (bare soils, vegetation canopies) reflect radiation quite anisotropically. Satellite measurements therefore strongly depend on both the position of the Sun and the position of the observer relative to the Sun, hence the term "bidirectional reflectance." This bidirectional reflectance field, however, cannot be expressed as a function of the relative geometry of illumination and observation only (for example, the two zenith angles and a relative azimuth angle), because it is also dependent on the physical and the morphological properties of the observed surface. This fact alone is responsible for some of the major difficulties encountered in the process of interpreting data from one satellite and, a fortiori, when trying to compare or combine measurements from the same ecosystem taken with different satellite sensors.

A model of the bidirectional reflectance of natural surfaces is therefore clearly needed. Various approaches have been used in the past to represent the anisotropy of the surface, including raytracing and Monte Carlo techniques [e.g., Kimes and Kirchner, 1982; Ross and Marshak, 1988], geometrical optics [e.g., Suits, 1972; Otterman, 1983], empirical functions [e.g., Walthall et al., 1985], semiempirical functions [e.g., Kieffer et al., 1977; Pinty and Ramond, 1986], and analytical solutions of the radiative transfer equations [e.g., Hapke, 1981; Camillo, 1987]. Each of these approaches exhibits specific advantages and disadvantages, depending on the particular applications for which they were designed. Ideally, what would be needed to extract pertinent information on land surfaces from satellite remote sensing data is a universal, accurate, and computationally cheap physically based model of the bidirectional reflectance of porous surfaces.

The goal of this paper is to describe a physically based model for predicting the bidirectional reflectance field over a radiatively homogeneous scattering surface. Specifically, our theoretical development is designed to describe a homogeneous full canopy composed of leaves. This model must be considered as the first necessary step toward a more realistic treatment of radiation scattering in this complex medium. The model is based on the scattering theory for a particulate media; it is kept as exact as reasonably possible, keeping in mind the necessary compromise between the need for an accurate description of the scattering process and for a simple analytical expression usable for the inversion of satellite remote sensing data. The application of this model to actual data sets is presented in a companion paper [Pinty et al., this issue].

This model follows the general approach developed by Hapke [1981, 1986]. Hapke's model was specifically designed to study planetary surfaces, using satellite bidirec-

tional measurements of their reflectance fields. Implicitly, his model is applicable to homogenous semi-infinite media composed of uniformly distributed scatterers, as is generally the case for soil surfaces. However, as a result of the availability of water on land, over 65% of the continental areas on Earth are covered by vegetation, and exhibit surfaces with radiative properties significantly different from bare soil cases. In the simplest case of a fully covering homogeneous canopy, the radiation is mainly reflected and absorbed by leaves which, for the purposes of modeling, can be considered flat surfaces. These surfaces, however, may be preferentially oriented (in zenith or azimuth angle), depending on the plant species, and it has been shown that the reflectance of the canopy is quite dependent on both the zenith angle of illumination and the statistical distribution of leaf orientation (see, e.g., Ross [1981], Dickinson [1983], and Verstraete [1987, 1988]). The theory described below is a generalization of Hapke’s model to account for the specific structure of a canopy, that is, the orientation of the leaves, as well as the characteristics of their geometrical arrangement in the canopy.

This paper also addresses another major theoretical point, namely, the mathematical expression of the combined transmission of the incoming and outgoing radiation. As will be seen shortly, the transmission of the scattered radiation in a porous medium is not independent of that of the incoming direct radiation: the two optical paths actually share a common volume, free of scatterers, near the scatterer that causes the reflection. Consequently, the optical depth along the combined path is reduced, and the total transmission becomes a function of the morphology of the medium. This effect results in an enhanced reflectance in the direction of illumination, and is known as the “hot spot” or the “opposition effect.” In practice, this increased reflectance expresses the total absence of apparent shadows to the sensor, when the direction of observation and the direction of illumination coincide, that is, when the source of radiation and the sensor are along the same optical path (see, e.g., Myneni et al. [1988]). This model therefore constitutes a direct attempt at providing a general analytical expression to relate some of the morphological properties of the canopy to the observed bidirectional reflectance field. Applications of this theory include the proper description of the reflectance (and in particular albedo) of a canopy of known physical and structural properties, as well as the capability to retrieve such information from remote sensing data.

2. Single Scattering of Direct Radiation in Plant Canopies

Absorption of solar radiation by plant canopies and at the soil surface is of great interest to atmospheric modelers and climatologists, since it determines to a large extent the amount of solar energy effectively available for the climate system as a whole. This absorption of radiative energy at the surface of the Earth is also of concern to agronomists and biologists because it directly affects the physiology and productivity of plants.

While the quantity of radiation actually absorbed in a given environment is difficult to estimate directly, the radiation scattered by the surface can be measured with standard instruments, either locally or remotely. Since the absorbed and the scattered components are directly related through the conservation of energy, it is customary to measure the scattered radiative energy and compute the absorption as a residual. It turns out, however, that many natural surfaces exhibit preferential directions for the reflection of solar radiation; in other words, the measured reflectance of such a surface depends not only on the nature and structure of the surface, or the intensity and position of the source of light, but also on the relative position of the observer. This represents a major inconvenience if the goal is to estimate the directional hemispherical reflectance (albedo) of the surface, since the reflectance must be measured and integrated over different viewing geometries. The bidirectional nature of the reflected radiation is an advantage, however, to the extent that it depends on (and therefore characterizes) the structure of the surface. This allows the retrieval of information on the surface by inversion of the measured reflectances in these viewing geometries.

This paper will focus on the theoretical treatment of the single-scattering component of the transfer of radiation through a vegetation canopy. This is amply justified by the facts that this component contributes approximately 90% of the total scattered radiation in the visible spectral band (that is, with a wavelength shorter than 0.7 µm) and about 40% of the radiation scattered in the near-infrared region, and that the single scattering of direct solar radiation contains the most useful information on the canopy structure, to the extent that the effect of multiple scattering is to smooth out such features. The inversion of actual data in the accompanying paper does take multiple scattering into account, however, following the improved formulation suggested by Dickinson et al. [1990].

2.1. Downward Transmission of the Direct Incident Radiation

We start by considering a horizontally homogeneous (but possibly vertically inhomogeneous) canopy of finite depth h above the ground. Let z denote the vertical coordinate, increasing upward from an origin at the bottom of the canopy. If θ1 and θ2 are the zenith and azimuth angles of the Sun, respectively, and if μ1 = cos θ1,

\[ T_1(z) = \exp \left[ -\frac{\tau_1(z)}{\mu_1} \right] = \exp \left[ -\int_{z}^{h} k_1(z) \Lambda(z) \, dz \right] \]

(1)

is the transmission of direct solar radiation through the canopy layers above level z. Here, \( τ_1(z) \) is the optical thickness of the canopy above level z, \( \Lambda(z) \) is the leaf area density, in m² m⁻³, at level z in the canopy, and \( k_1(z) \) is the extinction coefficient for direct radiation in this canopy:

\[ k_1(z) = \frac{\kappa_1(z)}{\mu_1} = \frac{\langle \cos \Theta_1 \rangle_z}{\cos \Theta_1} \]

(2)

where \( \Theta_1 \) is the angle between the normal to a leaf and the direction of the Sun, and \( \kappa_1(z) = \langle \cos \Theta_1 \rangle_z \) is the average of the cosine of this angle over all leaves at level z, a value that can be computed if the leaf orientation distribution function is known [e.g., Verstraete, 1987]. This average value is sometimes denoted \( G(\mu) \) [e.g., Ross, 1981].

If \( J_0 \) is the direct solar radiation flux available at the top of the canopy \( (z = h) \), in W m⁻², on a surface perpendicular to the direction of the Sun, in a given spectral band, then \( J = \)
$J_0 \mu_1$ is the direct solar radiation flux available at the top of the canopy, in W m$^{-2}$, on a horizontal surface, and $J_T(z)$ is the direct solar radiation flux transmitted to level $z$ without interception in the canopy [Verstraete, 1987, p. 10,991]. Following Hapke’s [1986, pp. 268-269] derivation, we express the flux of direct solar radiation transmitted to level $z - dz$ in this canopy as

$$JT_1(z - dz) = J_0 \mu_1 T_1(z) \exp \left[ - \int_{z - dz}^{z} \frac{\kappa_1(z) A(z)}{\mu_1} dz \right]$$

$$= J_0 \mu_1 T_1(z) \exp \left( - \frac{d \tau_1(z)}{\mu_1} \right)$$

where

$$d \tau_1(z) = \int_{z - dz}^{z} (\cos \Theta_1) z A(z) dz = \kappa_1(z) A(z) dz$$

where $\kappa_1$ is the average cosine of the angle between the normal to the leaf and the direction of illumination (see (2)). The amount of direct solar radiation interacting for the first time with the canopy in the slab $z$ to $z - dz$ is therefore

$$JT_1(z) - JT_1(z - dz) = J_0 \mu_1 T_1(z) \left[ 1 - \exp \left( - \frac{d \tau_1(z)}{\mu_1} \right) \right]$$

$$= J_0 \mu_1 T_1(z) \frac{d \tau_1(z)}{\mu_1} = J_0 T_1(z) d \tau_1(z)$$

(10)

(15)

(16)
action with it when it is scattered back exactly in the incoming direction. Moreover, direct solar radiation scattered back in directions characterized by small phase angles $g$, that is, close to its incoming path, has a high probability of escape from the canopy without further scattering by the vegetation. The transmission of the outgoing radiation is therefore not independent from the transmission of the incoming radiation. Reflectance is increased in the direction of illumination because no shadows are visible in that direction. This phenomenon is commonly observed on many porous surfaces such as soils and vegetation and is known as the “opposition effect” or “hot spot phenomenon.”

From this qualitative discussion, it follows that the opposition effect is a direct consequence of the structure of the canopy, and, in particular, that its angular extent is related to the shape of the “holes” between the leaves, that is, on the distribution of scatterer-free regions in the canopy as seen from the direction of the Sun.

Describing the transmission of direct solar radiation in a scattering medium as a negative exponential (such as in (1) and (14) above) is only a statistical statement that some diminishing fraction of the incoming photons will be able to penetrate further into the medium. Even though this law may be used to quantify the sunlit area as a function of depth in a canopy [e.g., Verstraete, 1987], it only describes the proportion of sun fleck area, not the number of sun flecks or their dimensions. Clearly, some additional parameter(s) on the canopy structure are needed to account for the hot spot, and they will of necessity be related to the geometry of the holes. Conversely, such parameter(s) will, in principle, permit the retrieval of information on the structure of plant canopies from an interpretation of the anisotropy of the reflectance field at small phase angles.

In the remainder of this section we derive a general expression of $T_2(z)$, for an arbitrary illumination and viewing geometry. This is achieved by finding an expression for the optical thickness of the return path (from the scatterer to the top of the canopy), which takes the above observations into account.

Consider a leaf of area $a_1$ and of arbitrary orientation ($\theta_1$, $\phi_1$), located at depth $z_1$ in the canopy, and partly illuminated by direct solar radiation. Let $a_1 \leq a$ be the illuminated area of this leaf. If $\Theta_2$ is the angle between the normal to the leaf and the direction of observation, the illuminated area effectively viewed by the observer is given by $a_1 \cos \Theta_2$, the projection of the illuminated area in a plane perpendicular to the direction of viewing. Furthermore, the observer would see the same illuminated area if in fact the leaf was horizontal, but had its lit area equal to $a_1 \cos \Theta_2 / \cos \theta_2$. It is therefore possible to replace all partly lit leaves with arbitrary orientation by equivalent (as far as the observer is concerned) horizontal leaves with a different illumination area, defined in such a way that the observer sees the same result. The following theory is therefore derived for horizontal leaves partially illuminated by the Sun.

For the purpose of deriving an analytical expression for the optical thickness of the scattered radiation, we will further assume that the equivalent horizontal lit area is circular (we are interested in describing the amount of light scattered in the direction of the observer, not the shape of the sun flecks on the leaves). Let $r$ be the radius of this small horizontal circular illuminated leaf area at level $z_1$ in the canopy. The lit circle and the direction of observation define a cylindrical volume $V_1$ in the canopy (Figure 1). Similarly, the lit circle and the direction of observation define the cylindrical volume $V_2$ in this canopy. These two cylinders share a common base and have the same height $(h - z_1)$ inside the canopy; therefore they have the same total volume:

$$V_1 = V_2 = \pi r^2(h - z_1)$$  \hspace{1cm} (16)

If the two directions of illumination and observation are identical, these two cylindrical volumes coincide. In all other cases, they intersect only over a finite height above the level of the scatterer, but since the two cylinders share the same lower base, they also necessarily always share some common volume

$$V_o = V_1 \cap V_2$$  \hspace{1cm} (17)

where $\cap$ designates the intersection of sets. The complement, that is, the fraction of $V_2$ not in common with $V_1$ is (Figure 1):

$$V_c = V_2 \setminus V_o$$  \hspace{1cm} (18)

where the symbol $\setminus$ designates the subtraction operation for sets.

Volume $V_1$, defined by the incoming beam of direct solar radiation, is free of scatterers by definition. Consequently, as long as the radiation scattered by the leaf in the direction of the observer remains within the volume $V_o$ common to both cylinders, the optical thickness is zero (transmissivity is one). The scattered radiation is, however, affected by the usual optical depth as soon as it leaves the common volume and proceeds to the observer within the volume $V_c$. Strictly speaking, each photon reaching the leaf and scattered in the direction of the observer has its own path length within $V_o$ and $V_c$, but we will assume that globally, the effective optical depth for all incoming direct solar radiation scattered toward the observer is a fraction of the optical depth that would be appropriate in the absence of additional information on the fractional path with zero optical depth, where the fraction is simply the relative proportion of the volume $V_c$ not in common with $V_1$:

$$\tau_2(z) = \frac{\|V_c\|}{\|V_2\|} \tilde{T}_2(z)$$  \hspace{1cm} (19)

where $\|\|$ stands for the actual volume occupied by the set $\mathcal{V}$.

When the two directions coincide, the entire volume of the cylinders is shared, $V_o = V_2$ and $V_c = 0$, hence the optical depth on the return path is $\tau_2 = 0$, and the transmission of the scattered radiation in the direction of illumination is $T_2(z) = 1$. Conversely, when the two directions are very different, the common volume $V_o$ is relatively small, and $V_c \approx V_2$, so that the optical depth in this case reduces to the asymptotic value $\tilde{T}_2$. Equation (14) for the transmission of the scattered radiation can therefore be rewritten

$$T_2(z) = \exp \left[ -\frac{\tau_2(z)}{\mu_2} \right] = \exp \left[ -\frac{\|V_c\|}{\|V_2\|} \tilde{T}_2(z) \right]$$  \hspace{1cm} (20)

and we are left with the problem of evaluating the ratio $\|V_c\|/\|V_2\|$ for arbitrary angular positions of the Sun and the observer.

2.4. Optical Thickness of the Scattered Radiation

We now define a new vertical coordinate, called $z'$, as the height in the canopy relative to the height of the scatterer:
Fig. 1. Geometry of illumination and observation of a horizontal partially illuminated leaf. 0 is the center of a circular sun fleck on a horizontal leaf. OA defines the normal to the leaf, which is vertical in this case. OB and OC are the directions of illumination and observation, respectively, characterized by zenith angles \( \theta_1 \) and \( \theta_2 \). See text for additional details.

\[ z' = z - z_l \]  

where \( z_l \) is the height of the leaf above an arbitrary base level, typically the ground.

Consider a horizontal plane a small variable distance \( z' \) above the level \( z_l \) of the scatterer. This plane intersects the two cylinders described above and thereby defines two circles (Figure 2). In the general case where the illumination and observation directions are different, these circles intersect. As the height \( z' \) of this plane increases above the level of the scatterer, the area of intersection between the two circles diminishes, until the level \( z' = z_M \) is reached where the two circles are tangent. For all levels above that, the two circles are disjoint. The volume common to both cylinders is defined by the integral of this common area over the vertical distance \( z' \).

Let \( \text{area}_C(z') \) be the area common to both circles at a height \( z' \) above the scatterer. It can be seen that

\[ \text{area}_C(z') = 2r^2(\alpha - \sin \alpha \cos \alpha) \]  

where \( \alpha = \alpha(z') \) is the angle between the direction joining the two centers of the circles and the radius joining one center and the point at which the circles intersect (Figure 3). Obviously, \( \alpha(z_M') = 0 \) and \( \text{area}_C(z_M') = 0 \) when the circles are tangent (or for all heights \( z' > z_M' \)), and \( \alpha(0) = \pi/2 \) and \( \text{area}_C(0) = \pi r^2 \) when the two circles overlap.

The angle \( \alpha \) is a simple function of the relative altitude \( z' \) above the scatterer, once the illumination and viewing angles are specified. Referring again to Figure 1, it can be seen that in the triangle \( OAB \), \( \alpha = z' \tan \theta_1 \) in the triangle \( OAC \), \( \alpha = z' \tan \theta_2 \), and in the triangle \( ABC \), \( BC^2 = AB^2 + AC^2 - 2AB AC \cos(\phi_1 - \phi_2) \). From these equalities, it results that the distance \( d \) between the centers of the two circles is given by

\[ BC = d = z'[\tan^2 \theta_1 + \tan^2 \theta_2 - 2 \tan \theta_1 \tan \theta_2 \cos(\phi_1 - \phi_2)]^{1/2} = z'G \]  

where

\[ G = [\tan^2 \theta_1 + \tan^2 \theta_2 - 2 \tan \theta_1 \tan \theta_2 \cos(\phi_1 - \phi_2)]^{1/2} \]  

when these circles intersect, that is, for \( 0 \leq z' \leq z'_M \). Clearly, if \( z' = z_M' \), the two circles are tangent and \( d = z_M'G = 2r \), so that

\[ z_M' = 2r/G \]  

Furthermore, for \( 0 \leq z' \leq z_M' \), that is, at all heights for which the two cylinders intersect, the distance between the two centers is also given by

\[ d = 2r \cos \alpha \]  

Combining (23) and (26), it is possible to express \( \alpha \) as a function of height:

\[ \alpha(z') = \cos^{-1}(d/2r) = \cos^{-1}(z'/G/2r) \]  

\[ = \cos^{-1}(z'/z_M) = \cos^{-1}\xi \quad 0 \leq z' \leq z_M' \]  

\[ \alpha(z') = 0 \quad z' > z_M' \]  

where \( \xi = z'/z_M \) is a convenient nondimensional variable taking up values between 0 and 1 over the vertical interval in which the cylinders intersect. Equation (22) can now be rewritten

\[ \text{area}_C(\xi) = 2r^2\cos^{-1}(\xi - \sin(\cos^{-1}\xi)\xi) \quad 0 \leq \xi \leq 1 \]  

\[ \text{area}_C(\xi) = 0 \quad \text{otherwise} \]  

The volume \( V_o \) common to \( V_1 \) and \( V_2 \) but inside the canopy can then be expressed as

\[ V_o = \int_0^{z'_\ast} \text{area}_O(z') \, dz' \]  

where \( z'_\ast = \min(z_M', z'_T) \), \( z'_T = h - z_l \) being the height of the top of the canopy above the scatterer, since we are inter-
Fig. 2. Top and side view of the intersection of the two cylinders representing the incoming and outgoing radiation beams, characterized by azimuth $\phi_1$ and $\phi_2$. See text for additional details.

estimated only in the optical depths within the canopy. Through a suitable change of variables, this can equivalently be expressed as

$$V_o = z_M \int_{0}^{\xi_T} s_h(\xi) \, d\xi = \frac{2r}{G} \int_{0}^{\xi_T} s_h(\xi) \, d\xi \quad (30)$$

where $\xi_0 = \min (1, \xi_T)$, with $\xi_T = z^T/z_M = (h - z_i)G/2r$ similarly defined as the level of the top of the canopy in the nondimensional variable $\xi$. Substituting (28) into (30), one obtains

$$V_o = \frac{2r}{G} \int_{0}^{\xi_T} 2r^2 [\cos^{-1} \xi - \sin^{-1} (\cos^{-1} \xi) \xi] \, d\xi \quad (31)$$

After some mathematical manipulations, this yields

$$V_o = \frac{4r^3}{G} \left[ \xi_T \cos^{-1} \xi_T - \frac{1 - \xi_T^2}{2} \right] \quad (32)$$

The notations can be simplified somewhat by introducing a new vertical coordinate $y = h - z_i$, the depth of the leaf from the top of the canopy. We now have $z^T = y$ and $\xi_T = yG/2r$. The complex expression (32) can be interpreted as follows. First, we note that as the observation direction $(\theta_2, \phi_2)$ tends toward the illumination direction $(\theta_1, \phi_1)$,

$$\lim_{2 \to 1} \xi_T = \xi_T = 0$$

$$\lim_{2 \to 1} G = 0$$

$$\lim_{2 \to 1} V_o = \pi r^2 y = V_1 = V_2$$

as it should. Second, if the two directions of illumination and observation are separate enough, the two cylinders intersect over a limited height only, and if the scatterer is deep enough in the canopy, the entire common volume $V_o$ should be within the canopy. These circumstances, which can be quantified as $\xi_T = yG/2r \geq 1$, yield

$$V_o = \frac{8r^3}{3G} \xi_T = 1 < \xi_T$$

Third, for leaf layers close enough from the top of the canopy, or for observation angles near the illumination angles,
since the cylinders defined by the illumination and observation directions intersect outside of the canopy in this case. These are the conditions leading to the observation of a hot spot, and it turns out that the common volume \( \mathcal{V}_o \), which controls the extent to which the transmission is unity on the return path, is simply a function of \( yG/2r \), which is nothing but a nondimensional shape factor, the ratio of the depth of the leaf from the top of the canopy to the diameter of sun flecks on the leaves. The shape of this hole is a function of the illumination and viewing geometry, and this variation is entirely contained in \( G \). This important fact is the basis for the expectation to be able to retrieve canopy structure information from hot spot observations in reflectance data sets, although further computations are needed before that result is achieved.

Comparing (34) and (35), and looking back at Figure 1, it appears that the common volume inside the canopy \( \mathcal{V}_o \) is the difference between the total volume common to \( \mathcal{V}_1 \) and \( \mathcal{V}_2 \), and the volume common to the two cylinders outside of the canopy. The expression

\[
\mathcal{V}_o = \frac{4r^3}{G} \left\{ \frac{yG}{2r} \cos^{-1} \left[ \frac{yG}{2r} \right] - \left[ 1 - \left( \frac{yG}{2r} \right)^2 \right]^{1/2} + \frac{1}{3} \sin^3 \cos^{-1} \left[ \frac{yG}{2r} \right] + \frac{2}{3} \right\} \tag{36}
\]

in (35) is therefore the negative of the volume common to the two cylinders outside the canopy.

Having computed the volume common to both cylinders, we now return to the problem of expressing the volume \( \mathcal{V}_c \) (equation (18)) needed to calculate the actual optical thickness of the scattered radiation:

\[
\tau_2(z) = \frac{\pi r^2 y}{\mathcal{V}_c} - \frac{yG}{2r} \cos^{-1} \left[ \frac{yG}{2r} \right] - \left[ 1 - \left( \frac{yG}{2r} \right)^2 \right]^{1/2} + \frac{1}{3} \sin^3 \cos^{-1} \left[ \frac{yG}{2r} \right] + \frac{2}{3} \tag{38}
\]

and it is seen that the correction to \( \tilde{\tau}_2 \) becomes negligible when \( \xi_T \) tends to large values, that is, when the two directions are far from each other \((G \to \infty)\) or for deeper layers \((y = (h - z_l) \to \infty)\).

Substituting \( \tau_2(z) \) back into (20) yields the value of the transmission for the radiation scattered off a single leaf. The reflectance observed by an instrument outside the canopy is of course the sum of the contributions of all leaves, so that a final vertical integral needs to be performed.

### 3. Bidirectional Reflectance of a Canopy

As seen in the previous section, the optical thickness on the return path takes on different expressions at different depths in the canopy. Accordingly, the vertical integral in (13) can be rewritten as follows:

\[
\rho(\theta_1, \phi_1; \theta_2, \phi_2) = \frac{\omega P(g)}{4\pi \mu_2} \int_{0}^{h} \cdots dy
\]

\[
= \frac{\omega P(g)}{4\pi \mu_2} \left\{ \int_{0}^{y_c} \cdots dy + \int_{y_c}^{h} \cdots dy \right\} = (\rho' + \rho^r) \tag{40}
\]

where the first integral takes into account all canopy layers which contribute strongly to the hot spot \((\xi_e = \xi_T < 1)\), while the second integral represents the contribution of deeper layers, for which the optical depth is always nonzero \((\xi_e = 1 < \xi_T)\). The variable \( y_c \) is given by

\[
y_c = \min (h, z_d) = \min \left( h, \frac{2r}{G} \right) \tag{41}
\]

and represents a threshold level: All leaf layers between the top of the canopy and \( y_c \) contribute directly to the hot spot by having at least a fraction of the light reaching the observer with a transmission equal to one in the canopy, while deeper layers \((y_c < y < h)\) are such that the transmission of scattered radiation always has a nonzero optical depth over some fraction of the path.

Using (38), the first contribution becomes

\[
\rho'(\theta_1, \phi_1; \theta_2, \phi_2) = \frac{\omega P(g)}{4\pi \mu_2} \int_{0}^{y_c} \exp \left[ -\frac{\kappa_1 \Delta y}{\mu_1} \right] \cdot \exp \left\{ \left[ 1 - \frac{4r}{\pi G} \right] \left[ \frac{yG}{2r} \cos^{-1} \left[ \frac{yG}{2r} \right] - \left[ 1 - \left( \frac{yG}{2r} \right)^2 \right]^{1/2} \right. \right.
\]

\[
+ \frac{1}{3} \sin^3 \cos^{-1} \left[ \frac{yG}{2r} \right] + \frac{2}{3} \left. \right\} \kappa_1 \Delta y \mu_2] dy
\]

\[
= \frac{\omega P(g) \kappa_1 \Delta y}{4\pi \mu_2} \int_{0}^{y_c} \exp \left[ -\frac{\kappa_1 \mu_2 + \kappa_2 \mu_1}{\mu_1 \mu_2} \Delta y \right] \tag{42}
\]

where \( \tau_1(z) = \kappa_1 \Delta y, dt_1 = \kappa_1 \Delta y, \) and \( \xi_e = \xi_T \). The analytical evaluation of such an integral is quite complicated.
For instance, the integral of the exponential of a single cosine is a Bessel function, and none of the tables of integrals we have consulted give any indication on the form of integrals even remotely resembling the one above. Since the complication originates from the form of the optical thickness \( r_2(z) \), it is reasonable to evaluate the relative contributions of the four terms in (38), but none of them is negligible with respect to the others in the range of values of \( \zeta_\infty \). On the other hand, it turns out that

\[
F(\zeta_\infty) = \frac{2}{\pi \zeta T} \left[ \zeta_\infty \cos^{-1} \zeta_\infty - (1 - \zeta_\infty^2)^{1/2} \sin^3 (\cos^{-1} \zeta_\infty) + \frac{2}{3} \right]
\]

(43)

is almost a linear function of \( \zeta_\infty \) over the range of interest (0 \( \leq \zeta_\infty \leq 1 \)), as can be seen from Figure 4. Since it is also desirable to have \( F(0) = 1 \) and \( F(1) = 4/3 \pi \) so that the optical thickness reaches exact values for extreme values of \( \zeta_\infty \) and connects smoothly with the case \( \zeta_\infty = 1 < \zeta_T \), we have adopted the following parameterization:

\[
\tilde{F}(\zeta_\infty) = 1 - \left( 1 - \frac{4}{3\pi} \right) \zeta_\infty
\]

(44)

which is also shown in Figure 4. This slight approximation seems justified by the high degree to which \( F(\zeta_\infty) \) is linear, and by the appreciable simplification it brings to the mathematical development. We now have

\[
\tau_2(z) = \left\{ 1 - \left[ 1 - \left( 1 - \frac{4}{3\pi} \right) \zeta_\infty \right] \right\} \tilde{r}_2(z)
\]

(45)

Equation (42) can then be rewritten as follows:

\[
\rho'(\theta_1, \phi_1; \theta_2, \phi_2) = \frac{\omega P(g)}{4\pi \mu_2} \int_0^{\pi/2} \exp \left[ -\kappa_1 \Lambda y \right] \left[ 1 - \left( 1 - \frac{4}{3\pi} \right) \zeta_\infty \right] \kappa_2 \Lambda y \kappa_1 \Lambda \ dy
\]

(46)

Conceptually, the size of the sun flecks on the leaves diminishes with depth in the canopy. This presents a serious complication, however, and we are going to assume that the integrals in (40) can be evaluated with a constant value of \( r_2 \), representative of an average sun fleck. This point will be discussed further in the next section. Carrying out the integrals, the first contribution yields

\[
\rho' = \frac{\omega P(g)}{4\pi \mu_2} \int_0^{\pi/2} \exp \left[ -\kappa_1 \Lambda y \right] \left[ 1 - \left( 1 - \frac{4}{3\pi} \right) \frac{\kappa_2 \Lambda y}{\mu_2} \right] \kappa_1 \Lambda \ dy
\]

(47)

where

\[
a = \left( 1 - \frac{4}{3\pi} \right) \frac{G \kappa_2 \Lambda}{2\mu_2}, \quad b = \frac{\kappa_1 \Lambda}{2\mu_2}
\]

(48)

The second integral is somewhat simpler. Using the optical thickness given by (39),

\[
\rho'' = \frac{\omega P(g)}{4\pi \mu_2} \int_0^{\pi/2} \exp \left[ -\kappa_1 \Lambda y \right] \left[ 1 - \left( 1 - \frac{4}{3\pi} \right) \frac{\kappa_2 \Lambda y}{\mu_2} \right] \kappa_1 \Lambda \ dy
\]

(49)

where \( \zeta_T \) has been replaced by its value \( yG/2r \).

Collecting all the terms and simplifying wherever possible, the expression for the bidirectional reflectance of a canopy for single scattering can be written as

\[
\rho(\theta_1, \phi_1; \theta_2, \phi_2) = \frac{\omega P(g)}{4\pi} \frac{\kappa_1 \mu_1}{\kappa_1 \mu_2 + \kappa_2 \mu_1} \left\{ \frac{\Lambda}{2} \frac{\kappa_1 \mu_2 + \kappa_2 \mu_1}{\mu_1 \mu_2} \left[ \frac{\pi}{a} \right]^{1/2} \exp \left( \frac{b^2}{a} \right) \right\}
\]

(50)
The parameter $\alpha$, used in $P_v(g)$ to describe the hot spot, is directly proportional to the geometric factor $G$, which tends to zero when the phase angle $g$ tends to zero. This does not reflect the dependence of the bidirectional reflectance of a deep canopy on the phases of the illuminated area; $A$, the leaf area density of the canopy, a measure of the density of leaf material; and the parameters $\kappa_1$ and $\kappa_2$, which describe the leaf orientation distribution for the illumination and viewing angles, respectively.

The bidirectional reflectance of shallow or sparse canopies is complicated by the contribution of the underlying soil, with its own anisotropy. Only deep (so-called semi-infinite) canopies will be considered in the rest of this and the accompanying paper [Pinty et al., this issue] unless stated otherwise. In this case, the last term of (50) vanishes, and the contribution of the soil can be neglected.

To account for multiple scattering in the canopy, a contribution that is important in the near-infrared spectral region, we followed the work of Dickinson et al. [1990]. Accordingly, the final expression for the bidirectional reflectance of a deep canopy is given by

$$
\rho(\theta_1, \phi_1; \theta_2, \phi_2) = \frac{\omega}{4\pi \kappa_1 \mu_1 + \kappa_2 \mu_2} \left[ P_v(g) P(g) + H(\mu_1/\mu_1) H(\mu_2/\mu_2) - 1 \right]
$$

where

$$
P_v(g) = \frac{\lambda}{2} \left( \frac{\mu_1 \mu_2}{\mu_1 \mu_2} \right) \left[ \frac{\pi}{a} \right]^{1/2} \exp \left( \frac{b^2}{a} \right) \left[ \text{erf} \left( \sqrt{\frac{2r}{G}} + \frac{b}{\sqrt{a}} \right) - \text{erf} \left( \frac{b}{\sqrt{a}} \right) \right]
$$

$$
+ \exp \left( \frac{4r}{3\pi \kappa_2 A} \right) \left[ \exp \left( \frac{\kappa_1 \mu_2 + \kappa_2 \mu_1}{\mu_1 \mu_2} \lambda \frac{2r}{G} \right) \right]
$$

and

$$
H(x) = \frac{1 + x}{1 + (1 - \omega)^{1/2} x}
$$

The parameter $a$, used in $P_v(g)$ to describe the hot spot, is directly proportional to the geometric factor $G$, which tends to zero when the phase angle $g$ tends to zero. This does not cause any singularity in the expression, however, because the difference in error functions tends to zero faster than the exponential diverges. In fact, the expression $P_v(g)$ varies between 2 and 1 for all values of the illumination and observation angles.

4. Discussion

From this derivation, it follows that the bidirectional reflectance of an homogeneous plant canopy can be described physically in terms of six optical and structural parameters. We now discuss some important points relative to the model and its physical interpretation.

First of all, it is important to remember that the radiation reflected by a canopy (or any surface, for that matter) has only penetrated a finite depth below the surface. The information retrieved from inverting the reflectances, using this or any other model of the surface, can therefore only yield the optical and the structural parameters of the upper canopy layers which actually affect the transfer of this radiation. If the bulk of the solar radiation cannot penetrate deeper than some fraction of the height of the canopy stand, it will be impossible, as a matter of principle, to retrieve any information on the lower portions of this canopy from the reflectances measured above the canopy. It is therefore difficult to retrieve the leaf area index from remote measurements in the solar spectral band, since either the canopy is very deep, in which case only the properties of the top can be retrieved, or the canopy is thin enough that even the lower leaf layers affect the transfer of radiation, but then the contribution of the reflectance from the soil must also be taken into account.

Another point to remember is that the canopy parameters $A$ and $r$ have been kept constant with height in the integrals (47) and (49). The assumption on $A$ is consistent with the hypothesis of an homogeneous canopy; the one on $r$ is more of a limitation and implies that the reflectance from a large number of sun flecks of different sizes is equivalent to the reflectance that would be observed if all the sun flecks had the same average size.

Of course, the actual size and shape of the sun flecks are functions of depth in the canopy, and depend on the size and shape of the holes between the leaves. These, in turn, are determined by the relative positions of the leaves in the canopy. As the beam of direct solar radiation penetrates the canopy, it gets broken down into smaller beams by the upper leaf layers, and each one of those smaller beams gets thinner due to the incremental blocking of additional leaves. It would be interesting, therefore, to relate the theoretical $r$ used in the previous section to measurable quantities of the canopy. One possible line of reasoning could be as follows.

Leaving aside the question of the number of sun flecks at any particular depth in the canopy, let $a(y)$ be the horizontal cross section of one of those solar beams, that is, the connected area that would be illuminated by direct solar radiation if a horizontal screen was placed at depth $y$ in the canopy. As discussed in section 2.3 and by Verstraete [1987], this cross section $a(y)$ decreases exponentially with depth $y$ in the stand:

$$
a(y) = A_0 \exp \left( -\frac{\kappa_1 A y}{\mu_1} \right)
$$

where $a_0$ is the area of the typical "hole" between the leaves at the top of the canopy. An estimate of the average value $\langle a \rangle$ of this area over a finite depth $y_t$ can be defined as

$$
\langle a \rangle = \frac{1}{y_t} \int_0^{y_t} a(y) \, dy = \frac{a_0 \mu_1}{\kappa_1 A y_t}
$$

where $y_t$ is the depth in the canopy after which a negligible fraction of the direct solar radiation is transmitted downward. From this expression, a typical radius of such an area can be estimated as
where \( r_0 \) is the radius of the "hole" between the leaves at the top of the canopy. Note that both \((a)\) and \((r)\) depend explicitly on the nondimensional product \( \lambda_{yt} \), which is in fact a ratio of two distances: \( y_t \) is a typical distance of penetration of direct solar radiation in the canopy, while \( \lambda \) is also the inverse of a typical distance between the leaves of a homogeneous canopy.

The relation between the parameter \( r \) in the model above and the typical radius of the holes \((\bar{r})\) is not simple, however, because the size of a sun fleck on a leaf cannot exceed the size of a leaf, by definition. To proceed further in this direction, one should adopt a particular model of canopy, to establish the nature of the relation between \( r, (r), \) and \( A \). Clearly, as the number of leaves per unit volume or the size of the leaves increases, the typical dimension of the "holes" between the leaves must decrease.

It is not so much the size of these voids that count, however, but rather their shape. Indeed, consider the following thought experiments: Let a canopy be described by \( n_i \) leaves per unit volume, and let \( a_l \) be the area of a leaf. Furthermore, let \( x_1, x_2, x_3 \) be the spatial coordinates of the centers of these uniformly distributed leaves. If we compress the unit volume vertically in such a way that the horizontal coordinates of the leaves remain unchanged \((x'_1 = x_1 \) and \( x'_2 = x_2 \)), and that the vertical coordinate is mapped into \( x'_1 = \xi x_1 \) with \( \xi < 1 \), and if additional leaves are then added in this portion of the unit volume at the new leaf density, then the leaf area index is increased, the average horizontal distance between the leaves is unchanged, but the vertical distance of penetration of light \( y_t \) is reduced. This is expected to produce a broader hot spot peak.

If, on the other hand, the compression is done horizontally \((x'_1 = \xi x_1, x'_2 = x_2, \) and \( x'_3 = x_3 \)), then the typical horizontal distance between the leaves is decreased, but the vertical distance between leaves is not affected. The hot spot produced by such a canopy would be sharper. Finally, if the number of leaves remains the same, but their area increases, as is the case during the growing season, then both the penetration depth \( y_t \) and the average distance between the leaves change and the response of the hot spot will depend on the change in the shape of the voids between the leaves. An analogous experiment has been performed by Ross and Marshak [1988] using a Monte Carlo model, and their results are consistent with our qualitative predictions.

As will be seen in the accompanying paper of Pinty et al. [this issue], (51) and (52) describe not only the general behavior of the bidirectional reflectance field of a canopy with arbitrary physical and morphological properties, but also correctly account for the hot spot phenomenon. It is important to realize that the genuine contribution of this new model lies in the proper accounting of the joint transmission of solar radiation in the canopy, both over the downward incoming path and over the upward outgoing path. Indeed, the quantitative description of the hot spot phenomenon derives directly from the correct accounting of this joint transmission over all possible angles of illumination and observations.

Pinty et al. [this issue] describe in detail the application of this model to actual data sets and discuss the capability of the model to reproduce specific patterns in the data.
